### 2.3.4. Historical Water Budget §354.18 (c)(2)

§ 354.18. (c) (2) Historical water budget information shall be used to evaluate availability or reliability of past surface water supply deliveries and aquifer response to water supply and demand trends relative to water year type. The historical water budget shall include the following:

- (A) A quantitative evaluation of the availability or reliability of historical surface water supply deliveries as a function of the historical planned versus actual annual surface water deliveries, by surface water source and water year type, and based on the most recent ten years of surface water supply information.
- (B) A quantitative assessment of the historical water budget, starting with the most recently available information and extending back a minimum of 10 years, or as is sufficient to calibrate and reduce the uncertainty of the tools and methods used to estimate and project future water budget information and future aquifer response to proposed sustainable groundwater management practices over the planning and implementation horizon.
- (C) A description of how historical conditions concerning hydrology, water demand, and surface water supply availability or reliability have impacted the ability of the Agency to operate the basin within sustainable yield. Basin hydrology may be characterized and evaluated using water year type.

The historical surface water and groundwater budgets for the Tule Subbasin are shown in Tables 2-2a, 2-2b, and 2-3 and described in Sections 2.3.1 and 2.3.2. Historical surface water and groundwater budgets for each of the six GSAs in the subbasin are provided in:

- Appendix A LTRID GSA.
- Appendix B ETGSA
- Appendix C DEID GSA
- Appendix D Pixley GSA
- Appendix E Tri-County Water Authority GSA
- Appendix F Alpaugh GSA

Sources of surface water supply to agriculture in the Tule Subbasin include diverted stream flow from the Tule River and Deer Creek and imported supplies delivered via the Friant-Kern Canal, State Water Project, and other diverted streamflow from streams located outside the subbasin (i.e. King's River). A comparison of water rights and annual water deliveries for the 10-yr period from 2007/08 to 2016/17 is provided for the Tule River and Friant-Kern Canal in Table 2-5. As shown, total Tule River water diversions during the 10-yr period are approximately 90 percent of the sum of diversion rights over that period. The primary reason for this is that the 10-yr period from 2007/08 to 2016/17 was relatively dry with precipitation approximately 69 percent of long-term average (see Figure 2-28). Friant-Kern Canal deliveries to agencies with contracts within the Tule Subbasin have also been below the sum of Class I and Class II contract amounts for most of the 10-yr period. However, many contractors sell a portion of their available supply from the canal to other agencies. Likewise, some contractors (e.g. Kern-Tulare Water District) purchase additional supplies from the canal from other contractors. Thus, while precipitation trends do effect the

volume of water available to Friant-Kern Canal contractors (the precipitation amounts during the 10-yr period from 2007/08 to 2016/17 are below average), it is difficult to compare planned versus actual deliveries based on these data.

The primary surface water supply issue affecting the ability of agencies to operate within the Sustainable Yield of the subbasin is reduced delivery capacity in the Friant-Kern Canal due to land subsidence. Land subsidence has lowered the canal elevation in certain areas resulting in a reduction in downstream canal delivery capacity. Reduced deliveries due to land subsidence can result in greater groundwater pumping to meet agricultural water demand. While the reduced supply capacity of the Friant-Kern Canal is not the primary reason for the overdraft observed in the Tule Subbasin from 1986/87 to 2016/17, it is a contributing factor.

### 2.3.5. Projected Water Budget §354.18 (c)(3)

A projected water budget for the Tule Subbasin has been developed to incorporate the planned projects and management actions of each of the six GSAs for achieving sustainability (see Tables 2-6 and 2-7). The projects and management actions were incorporated into the groundwater flow model of the Tule Subbasin for the projected time period from 2020 to 2070 in order to assess the sustainability of the planned actions, assess the interaction of the planned actions on groundwater levels between the GSAs, and estimate the Sustainable Yield of the subbasin. The model projection also incorporated adjustments to the hydrology and water deliveries to account for potential climate change. The final projected water budget is the one that produced the 50<sup>th</sup> percentile Sustainable Yield estimate (see Section 2.3.2.7 herein). The projected surface water and groundwater budgets are shown in Tables 2-8a, 2-8b, and 2-9. Projected water budgets for each of the six GSAs are provided in Appendices A through F.

Baseline Tule River flows, Friant-Kern Canal deliveries, and the State Water Project's California Aqueduct deliveries used in the future projection for the model were adjusted to account for projections of future climate change. Adjustments were applied based on output from the DWR's CalSim-II model, which provided adjusted historical hydrology for major drainages and imported supplies based on scenarios recommended by the DWR Climate Change Technical Advisory Group. Climate change adjustments to hydrology and surface water deliveries were applied over two time periods within the SGMA planning horizon, as defined by California Water Commission (2016)<sup>2</sup>:

1. A 2030 central tendency time period, which provides near-term projections of potential climate change impacts on hydrology, centered on the year 2030, and

<sup>&</sup>lt;sup>2</sup> California Water Commission, 2016. Technical Reference – Water Storage Investment Program. Dated November 2016.

<sup>&</sup>lt;sup>1</sup> DWR Climate Change Technical Advisory Group, 2015. Perspectives and Guidance for Climate Change Analysis. DWR Technical Information Record.

2. A 2070 central tendency time period, which provides long-term projections of potential climate change impacts on hydrology, centered on the year 2070.

For imported water supplies from the Friant-Kern Canal, TH&Co utilized projected delivery schedules from the Friant Water Authority (Friant Water Authority, 2018). The projected water deliveries include adjustments to supplies associated with the planned San Joaquin River Restoration Project (SJRRP). Adjustments to Friant-Kern Canal supplies to account for climate change and SJRRP were applied beginning in 2025. The adjustments were applied incrementally between 2025 and 2030 such that the full adjustments were in effect in 2030. TH&Co applied the 2070 central tendency time period climate-related adjustments to imported water deliveries in the Tule Subbasin model projection for the period from 2050 to 2070.

## 2.4 Management Areas §354.20

§ 354.20. Management Areas

(a) Each Agency may define one or more management areas within a basin if the Agency has determined that creation of management areas will facilitate implementation of the Plan. Management areas may define different minimum thresholds and be operated to different measurable objectives than the basin at large, provided that undesirable results are defined consistently throughout the basin.

Of the six GSAs within the Tule Subbasin, five have identified separate management areas within their boundaries (see Figure 2-33). The management areas are as follows:

#### LTRID GSA

Agricultural Management Area Municipal Management Area Tulare County MOU Management Area

#### **ETGSA**

Porterville Community Management Area Terra Bella Community Management Area Ducor Community Management Area Kern-Tulare Management Area Greater Eastern Tule Management Area

#### **DEID GSA**

Delano-Earlimart Irrigation District Management Area Western Management Area Richgrove Community Services District Management Area

Earlimart Public Utilities District Management Area

#### **Pixley GSA**

Pixley Irrigation District Management Area Pixley Public Utilities District Management Area Teviston Management Area

#### **Tri-County Water Authority GSA**

North Management Area Southeast Management Area

In addition to the management areas identified for each GSA, a separate ETGSA Land Subsidence Monitored Area (ETGSA Monitored Area) has been identified for the eastern portion of the subbasin in the vicinity of the Friant-Kern Canal (see Figure 2-36; TH&Co, 2021). This ETGSA Monitored Area was developed based on the extent of historical land subsidence observed along the Friant-Kern Canal, including model results of cumulative land subsidence calibrated to historical land subsidence rates measured from InSAR satellite data. The ETGSA Monitored Area covers most of the ETGSA. The basis for the eastern and northern boundaries of the ETGSA Monitored Area is the limit of land subsidence detected by the 2015 – 2018 InSAR land subsidence map. This area is considered recently active and prone to continued subsidence in the future. These boundaries are approximately two to three miles east of the communities of Ducor and Terra Bella and approximately one mile north of the Tule River at the FKC. The western and southern boundaries of the ETGSA Monitored Area are the western and southern boundaries of the ETGSA. Also, the southeast portion of the Pixley Irrigation District GSA is included in the monitored area based on an agreement with the Friant Water Authority and ETGSA.

It is also noted that a portion of the ETGSA Monitored Area has been set aside as the ETGSA Managed Area (see Figure 2-36) where more urgent management actions may be needed to meet the land subsidence management goals. The ETGSA Managed Area was identified based on InSAR satellite data and groundwater flow model analysis of land subsidence. The ETGSA Managed Area extends two miles on either side of the Friant-Kern Canal from the Tule River to the southern boundary of the ETGSA. Management actions within this area will be separate from, and may be different than, planned management actions published in the ETGSA GSP for the greater ETGSA.

#### 2.4.1 Criteria for Management Areas §354.20 (b)(1)

§ 354.20. (b) A basin that includes one or more management areas shall describe the following in the Plan:

(1) The reason for the creation of each management area.

The majority of the management areas are associated with communities that provide municipal water supply. These communities have been delineated separately because the beneficial use of the groundwater produced within the management areas (municipal supply) is different than the beneficial use of groundwater across the majority of the subbasin (agriculture). Other management areas were identified for portions of the subbasin with unique hydrogeology and areas where access to imported water is different than other portions of the GSA in which they are located.

Management Areas categorized under the Community Management Area Type have been created to specifically address the needs of the Tule Subbasin's population centers and communities. Future projects and management actions focused in these areas will seek to achieve the Tule Subbasin sustainability goal and improve access to safe, reliable drinking water supplies. The boundaries for each Community Management Area consider existing County and/or City adopted Urban Development Boundaries, as well as the service area boundaries of the public water suppliers providing services to residents within these areas.

In addition to community management areas, LTRID GSA has delineated a management area, the Tulare County MOU Management Area, associated with lands outside and to the southwest of the LTRID service area that were annexed to the LTRID GSA (see Figure 2-33). This management area was formed because it does not have the same access to surface water deliveries as the LTRID service area and, therefore, will require separate management actions than the rest of the GSA.

ETGSA has delineated a separate management area for the Kern-Tulare Water District (Kern-Tulare Management Area). Wells from this area produce groundwater primarily from a deeper and separate aquifer system (i.e. Pliocene Marine and Santa Margarita Formation) than other parts of the ETGSA. Groundwater level conditions in wells in this area are different than other areas of the ETGSA. Additionally, the service area of Kern-Tulare Water District is divided between the Tule and Kern County Subbasins. Future projects and management actions in this Management Area will focus on enabling Kern-Tulare Water District to achieve the sustainability goals of both the Tule and Kern County Subbasins while minimizing the need to alter its operations. As such, Kern-Tulare Water District has developed their own monitoring plan for their service area.

DEID GSA has delineated a management area, the Western Management Area, associated with lands outside and to the west of the DEID service area. These lands were annexed to the DEID GSA. This Western Management Area was formed because it does not have the same access to surface water deliveries from the Friant-Kern Canal as the DEID service area and, therefore, will require separate management actions than the rest of the GSA.

TCWA GSA has delineated two separate management areas, the North and Southeast Management Areas. The North Management Area receives surface water and groundwater on the lands located within the Angiola Water District. It is noted that some areas within the North Management Area are outside the Angiola Water District but are included in the management area due to their

proximity to Angiola Water District. The Southeast Management area is an undistracted area dependent on groundwater.

## 2.4.2 Minimum Thresholds and Measurable Objectives §354.20 (b)(2)

§ 354.20. (b) (2) The minimum thresholds and measurable objectives established for each management area, and an explanation of the rationale for selecting those values, if different from the basin at large.

#### 2.4.2.1 Minimum Thresholds

Minimum thresholds and measurable objectives for each groundwater level and land subsidence representative monitoring site in each GSA are shown on the hydrographs and in the tables provided in Appendices A through F. The rational for determining the minimum thresholds and measurable objectives are not different by management area within a GSA.

### 2.4.3 Monitoring Plan §354.20 (b)(3)

§ 354.20. (b) (3) The level of monitoring and analysis appropriate for each management area.

The Tule Subbasin Technical Advisory Committee has developed a subbasin-wide monitoring plan, which describes the monitoring network and monitoring methodologies to be used to collect the data to be included in Tule Subbasin GSPs and annual reports. The subbasin-wide monitoring plan is included as Attachment 1 to the Coordination Agreement. Separate monitoring networks have been established for groundwater levels (see Figure 2-34), groundwater quality (see Figure 2-35), land subsidence (see Figure 2-36) and surface water (see Figure 2-7). For each monitoring network, the monitoring plan describes the monitoring features included in the plan, the monitoring procedure to be followed to collect the data, and the monitoring frequency. The monitoring plan also includes an assessment of data gaps and a data management plan.

A subset of groundwater level monitoring features in the monitoring plan have been identified as representative monitoring sites to be relied on for the purpose of assessing progress with respect to groundwater level sustainability in the subbasin. The representative groundwater level monitoring sites are shown on Figure 2-34. At least one representative groundwater level monitoring site has been identified within each management area. Where possible based on available wells, representative monitoring sites have been chosen with perforations exclusively in either the Upper or Lower Aquifer. To provide adequate spatial coverage of the subbasin, some representative monitoring sites include perforations across multiple aquifers until new monitoring features can be constructed. Representative groundwater level monitoring wells will be equipped with pressure transducers to measure groundwater levels on a daily basis.

A land surface elevation monitoring network has also been established and is shown on Figure 2-36. The monitoring network consists of 94 benchmarks installed in 2020 and 2021. Each benchmark is a representative monitoring site for land subsidence. The elevations of the benchmarks are surveyed annually..

### 2.4.4 Coordination with Adjacent Areas §354.20 (b)(4)

§ 354.20. (b) (4) An explanation of how the management area can operate under different minimum thresholds and measurable objectives without causing undesirable results outside the management area, if applicable.

The minimum thresholds described in each GSA's GSP have been informed through an analysis of potential future groundwater levels in the subbasin using a numerical groundwater flow model that incorporates future planned projects and management actions of each of the GSAs. The minimum thresholds have been developed such that maintenance of groundwater levels above those levels should preserve beneficial uses of the groundwater and prevent undesirable results with respect to groundwater levels, groundwater storage, and land subsidence within the management area, GSA and adjacent areas. Management of the Tule Subbasin is adaptive. As management actions and projects are implemented throughout the subbasin and as additional data are collected through the Tule Subbasin Monitoring Plan, minimum threshold values and measurable objectives may change. Changes to basin management to address undesirable results will be conducted through the Tule Subbasin TAC in accordance with the Tule Subbasin Coordination Agreement.

Soil Map Figure 2-8

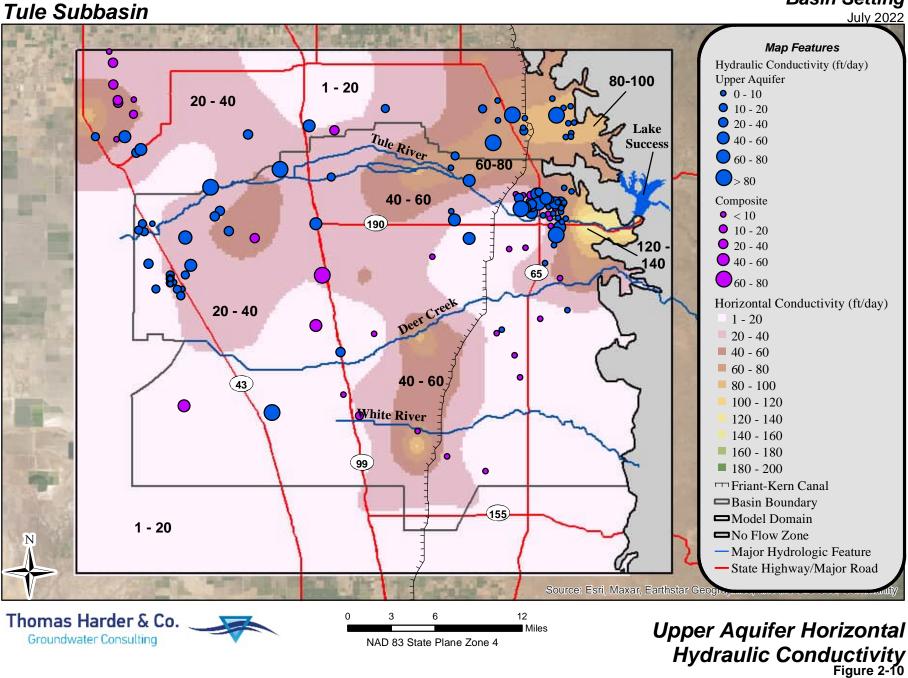

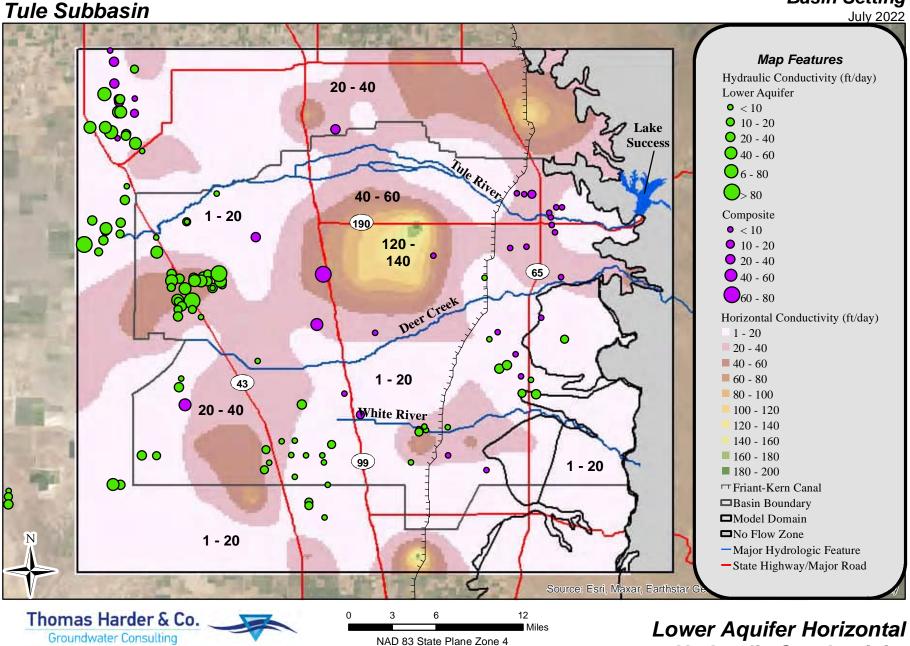

The Soil Agricultural Groundwater Banking Index (SAGBI) is a suitability index for groundwater recharge on agricultural land. It is based on five factors: deep percolation, root zone residence time, topography, chemical limitations, and soil surface condition.

Recharge Basins and Favorable Areas for Recharge

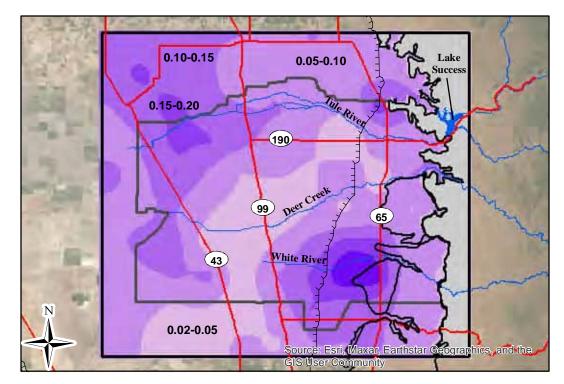

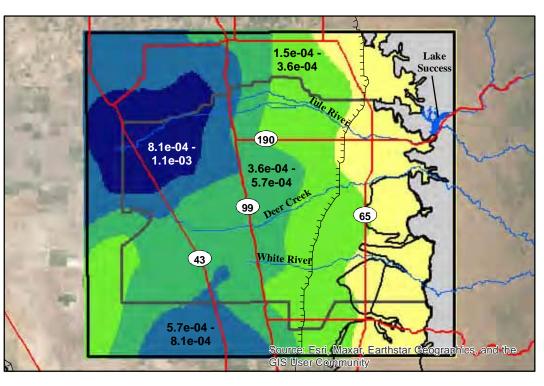

Lower Aquifer Horizontal
Hydraulic Conductivity
Figure 2-11

#### Specific Yield

#### Storativity

Note: Specific Yield values apply to areas of the subbasin where groundwater levels are below the top of the aquifer (primarily the east side of the subbasin). Storativity values apply to areas of the subbasin where groundwater levels are confined beneath the Corcoran clay or other confining beds.

#### Map Features

Specific Yield (Under Unconfined Conditions)

- 0.02 0.05
- 0.05 0.10
- 0.10 0.15
- 0.15 0.20
- 0.20 0.25

Storativity (Under Confined Conditions)

- 8.0e-06 1.5e-04
- 1.5e-04 3.6e-04
- 3.6e-04 5.7e-04

# Groundwater Flow Model of the Tule Subbasin

January 2020

Prepared for

Tule Subbasin MOU Group

Prepared by

Thomas Harder, PG, CHG

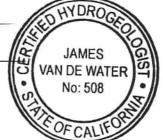

THOMAS E. HARDER No: 588

**Principal Hydrogeologist** 

Benjamin Lewis, PG, CHG

Senior Hydrogeologist

Jim Van de Water, PG, CHG Principal Hydrogeologist

# **Table of Contents**

1.0 Int	troduction	1
1.1	Background	1
1.2	Groundwater Flow Model Objectives	1
1.3	Model Domain	2
1.4	Model Development Approach	3
1.5	Types and Sources of Data	4
2.0 Hy	drogeologic Conceptual Model	7
2.1	Geology	7
2.2	Hydrology	8
2.3	Hydrogeology	10
2.4	Land Subsidence	11
3.0 Gr	oundwater Flow Model	13
3.1	Description of Model Codes	13
3.2	Model Size and Grid Geometry	13
3.3	Temporal Discretization	13
3.4	Water Budget Areas	14
3.5	Agricultural Water Use	14
3.5	Estimates of Total Agricultural Irrigation Demand	14
3.5	Estimates of Individual Water Supplies to Meet Irrigation Demand	16
3.6	Boundary Conditions.	16
3.6	Lateral Model Boundaries	16
3.6	5.2 Layer Elevations	17
3.6	Groundwater Level Initial Conditions	18
3.6	5.4 Groundwater Recharge	18
3.6	G.5 Groundwater Pumping	19
3.7	Aquifer Characteristics	20
3.7	7.1 Transmissivity and Hydraulic Conductivity	20
3.7	7.2 Storage Properties	21

	3.7.	.3	Critical Hydraulic Head	22
3	.8	Mod	del Calibration	23
	3.8.	.1	Calibration Targets for Groundwater Levels	23
	3.8.	.2	Calibration Targets for Land Subsidence	24
	3.8.	.3	Calibration Process	24
	3.8.	.4	Calibration Results	25
4.0	Fut	ture S	Subbasin Management Scenario for Analysis with the Model	29
4	.1	Proj	ects and Management Actions	29
4	.2	Assı	umptions for Municipal Pumping	29
4	.3	Assı	umptions for Hydrology and Surface Water Deliveries on Major Streams	29
4	.4	Assı	umptions for Friant-Kern Canal Deliveries	30
5.0	Ana	alysis	of the Future Subbasin Management Scenario	32
5	.1	Proj	ected Groundwater Budget	32
5	.2	Proj	ected Groundwater Levels	32
	5.2.	.1	2020 – 2040 Transitional Pumping Period	33
	5.2.	.2	2040 – 2050 Sustainability Period	33
	5.2.	.3	2050 – 2070 Sustainability Period with Extended Climate Adjustments	33
5	.3	Proj	ected Land Subsidence	34
5	.4	Sust	ainable Yield	34
5	.5	Unc	ertainty Analysis	37
	5.5.	.1	Uncertainty in Sustainable Yield Estimate	37
	5.5.	.2	Uncertainty in Friant-Kern Canal Subsidence	38
6.0	Sun	nmaı	ry of Findings	40
7.0	Ref	eren	ces	42

TRA – Tule River Association

USBR – United States Bureau of Reclamation

USGS – United States Geological Survey

UWMP - Urban Water Management Plan

WBA – Water Budget Area

#### 1.0 Introduction

## 1.1 Background

In order to assist in groundwater basin management planning and inform the preparation of Groundwater Sustainability Plans (GSPs) as required by the Sustainable Groundwater Management Act (SGMA), the Tule Subbasin Technical Advisory Committee (TAC) commissioned the preparation of a numerical groundwater flow model (GFM) of the Tule Subbasin. The Tule Subbasin is approximately 733 square miles located in the southwestern portion of Tulare County within the southern San Joaquin Valley Groundwater Basin (CDWR, 2003; see Figure 1). The Subbasin is divided into seven Groundwater Sustainability Agencies (GSAs):

- 1. Lower Tule River Irrigation District GSA
- 2. Pixley Irrigation District GSA
- 3. Eastern Tule GSA
- 4. Delano-Earlimart Irrigation District GSA
- 5. Tri-County Water Authority GSA
- 6. Alpaugh Irrigation District GSA
- 7. County of Tulare GSA Tule

It is noted that the entire geographic area of the Subbasin is covered and managed by the first six GSAs. While the County of Tulare GSA is responsible for some lands within the Tule Subbasin, these areas are managed by the other GSAs through agreements. As such, this report presents results relating to the areas of the first six GSAs listed above.

Utilization of a calibrated groundwater flow model is a CDWR Best Management Practice (BMP) for developing GSPs to comply with SGMA. A BMP "... refers to a practice, or combination of practices, that are designed to achieve sustainable groundwater management and have been determined to be technologically and economically effective, practicable, and based on best available science." (GSP Regulations, §351[i]). Prior to preparing the GFM, TH&Co prepared a detailed hydrogeologic conceptual model (BMP No. 3) and water budget (BMP No. 4) of the Tule Subbasin. These documents provide the foundational information on which the GFM is based.

## 1.2 Groundwater Flow Model Objectives

The GFM was prepared to address the following:

- Validate the preliminary Subbasin-wide groundwater and surface water budget and, as necessary, refine the least-known elements of the water budget via model calibration;
- Evaluate the Subbasin-wide Sustainable Yield estimate based on a future projection of groundwater projects, management actions, and climate change;
- Develop water budget estimates for each of the six GSAs of the Subbasin, which incorporates historical hydrological data, surface water rights specific to the individual GSAs, and future projections of groundwater pumping and imported water; and
- Evaluate historical land subsidence in the Subbasin and predict future land subsidence in areas of critical infrastructure.

#### 1.3 Model Domain

The model domain is the three-dimensional volume of hydrogeologic media evaluated by the model. Based on the objectives of the GFM, and in consideration of potential impacts of pumping and recharge outside the Tule Subbasin boundaries on the water budget within the Tule Subbasin, the lateral model area was selected as shown on Figure 2. This model area extends approximately five to ten miles north of the northern Tule Subbasin boundary, four miles west of the western boundary, three to six miles south of the southern Tule Subbasin boundary, and a few miles into the Sierra Nevada Mountains on the east. The area of the Sierra Nevada Mountains between the alluvial/bedrock interface and eastern model boundary is inactive. The total model area is 1,472 square miles and the active model area is approximately 1,320 square miles (i.e., approximately 845,000 acres).

The vertical model domain was developed to simulate groundwater flow in the primary aquifers and aquitards that were identified in the conceptual model of the Tule Subbasin. Accordingly, the model consists of five layers of variable thickness throughout the model domain based on cross-sections developed from the conceptual model. The layers are described as follows:

- Layer 1 simulates groundwater flow in the upper unconfined aquifer;
- Layer 2 is an underlying comparatively low permeability unit separating the upper and lower aquifers and generally coincides with the Corcoran Clay west of Highway 99;
- Layer 3 simulates groundwater flow in the lower aquifer. This layer is semi-confined in the east and confined below the Corcoran Clay in the west;
- Layer 4 simulates groundwater flow in the Pliocene marine deposits between the overlying lower aquifer and, in the eastern portion of the Subbasin, the underlying Santa Margarita Formation aquifer;
- Layer 5 simulates groundwater flow in the Santa Margarita Formation aquifer in the eastern portion of the Subbasin.

# 1.4 Model Development Approach

The process for developing the groundwater flow model was consistent with standard procedures outlined in literature and other guidelines (Anderson and Woessner, 1992; ASTM, 1993; CDWR, 2016). The process is outlined in Figure 3 and included:

- **1.** <u>Identification of the Model Domain</u>. The model domain was selected to encompass the entire Tule Subbasin as described in Section 1.3 (see Figure 2). The model domain was presented to the Tule Subbasin TAC in TH&Co (2017a).
- **2.** <u>Identification of the Model Software.</u> TH&Co selected a model code with capabilities to address the modeling objectives and provide a foundation for future model updates and applications. A detailed description of the model code and suite of modeling tools selected for the Tule Subbasin groundwater flow model are provided in Section 3.1 of this report. Selection of the model software was presented to the Tule Subbasin TAC in TH&Co (2017a).
- **3.** <u>Data Compilation and Review.</u> It was necessary to compile and review geological, hydrological, hydrogeological, and other data (see Section 1.5) to develop the hydrogeologic conceptual model and provide data for calibration targets and boundary conditions. Compiled data was organized and stored in a database for easy access and analysis.
- **4.** <u>Hydrogeologic Conceptual Model Development.</u> The conceptual model was developed through the generation of hydrogeologic cross sections, groundwater contour maps, hydrographs, pumping test data, and groundwater quality data. The data analyses resulted in determination of model boundary conditions, layers, initial groundwater levels, and an initial aquifer parameter distribution. The hydrogeologic conceptual model was presented to the Tule Subbasin TAC in TH&Co (2017b).
- 5. <u>Development of Preliminary Surface Water and Groundwater Budgets.</u> Streamflow, surface water imports, evapotranspiration data, land use, groundwater underflow, groundwater pumping, and other hydrogeologic data were compiled into comprehensive surface water and groundwater budgets. The water budgets provided initial flux estimates for input into the groundwater flow model. The preliminary detailed historical surface water

and groundwater budgets were presented to the Tule Subbasin TAC in TH&Co (2017b), prior to development of the numerical model.

- **6.** <u>Selection of the Calibration Period.</u> The model calibration period was selected based on the quality and quantity of data available for development of the conceptual model and preliminary water budget. Using this criterion, the transient period for calibration was selected to be October 1986 through September 2017.
- 7. <u>Numerical Model Development.</u> Data and analyses from the conceptual model were converted into a form suitable for input into the numerical model. This included designing the model grid, determining the simulation stress periods, importing layer boundaries, developing model input files for the various hydrogeological stresses (e.g. groundwater production and recharge), and importing initial aquifer parameter zones.
- **8.** <u>Model Calibration.</u> The process of model calibration involved adjusting aquifer properties and stresses until an acceptable match was obtained between measured groundwater levels and simulated groundwater levels. Simulated changes in land surface elevation were also calibrated to data from Global Positioning System (GPS) stations and satellite data.
- **9.** <u>Sensitivity Analysis.</u> A sensitivity analysis was conducted to assess the impact of varying aquifer properties and stresses on the model calibration.
- **10.** <u>Uncertainty Analysis.</u> Using Sustainable Yield as the metric for evaluating model uncertainty, TH&Co developed a range in potential Sustainable Yield values from over 200 calibrated realizations of the model. The range in potential Sustainable Yield represented the uncertainty in the model.

# 1.5 Types and Sources of Data

Compilation, review and analysis of multiple types of data were necessary to develop the groundwater flow model. The various types of data are summarized in Figure 4 and include geology, soils/lithology, hydrogeology, surface water hydrology, climate, crop types/land use, topography, and groundwater recharge and recovery. Groundwater levels, well construction information, groundwater quality, and pumping test data were stored in a relational database. Other types of data necessary for analysis were compiled into spreadsheets.

Data for the development of the groundwater flow model were obtained from multiple sources:

<u>Geological Data</u> including geologic maps and cross sections were obtained from the United States Geological Survey (USGS) and the California Geological Survey (CGS).

<u>Soils/Lithological Data</u> including detailed lithologic logs from wells and test boreholes, geophysical logs, and driller's logs from wells and test boreholes from the CDWR, the USGS, the City of Porterville, the California Division of Oil, Gas and Geothermal Resources (DOGGR), and various local irrigation districts.

<u>Hydrogeologic Data</u> including groundwater levels and pumping tests were obtained from the CDWR, Lower Tule River Irrigation District (LTRID), Deer Creek and Tule River Authority (DCTRA), Angiola Water District (AWD), the City of Porterville, Kern-Tulare Water District (KTWD), DEID, and the California Statewide Groundwater Elevation Monitoring (CASGEM) website.

<u>Groundwater Recharge and -Pumping Data</u> including spreading basin locations and dimensions, artificial recharge, water well construction, well locations, groundwater production, surface water diversions, canal losses, and river losses were obtained from LTRID, Pixley Irrigation District, DEID, AWD, CDWR, Porterville Irrigation District, Tule River Association (TRA) annual reports, and DCTRA annual reports.

<u>Hydrological (i.e., Surface Water) Data</u> consisted of stream gage data along the Tule River, Deer Creek, and White River were obtained from the USGS, DCTRA reports and TRA annual reports. Imported water deliveries were obtained from LTRID, Pixley ID, DEID, KTWD, AWD, and the United States Bureau of Reclamation (USBR).

<u>Climate Data</u> was acquired from CDWR's California Irrigation Management Information System (CIMIS), TRA reports, and the Western Regional Climate Center website.

<u>Land Use Data</u> was obtained from the CDWR, LTRID, Pixley ID, Porterville ID, Saucelito ID, and the USGS Earth Resources Observation and Science Center. Political boundaries were obtained from the California Cal-Atlas Geospatial Clearinghouse and the LTRID.

<u>Topographical Data</u> including Digital Elevation Models (DEMs), topographical maps, GPS data, and Interferometric Synthetic Aperture Radar (InSAR) satellite data were acquired from the USGS, CDWR, and National Aeronautics and Space Administration (NASA) Jet Propulsion Laboratory (JPL).

In addition to the various types of data, TH&Co reviewed numerous historical reports on the geology, hydrogeology and groundwater management of the model area. These reports included

USGS publications, CDWR reports and bulletins, consultant reports and academic publications. Publications relied on for the model preparation are summarized in the References (Section 7).

# 2.0 Hydrogeologic Conceptual Model

The hydrogeologic conceptual model is a description of the groundwater flow system of the Tule Subbasin and how it interacts with surface water and land use of the area. The conceptual model includes a description of the geologic setting, boundary conditions, principal aquifers, and aquitards. The hydrogeologic conceptual model for the GFM domain is addressed in detail in TH&Co (2017b). This section presents a summary of the hydrogeologic conceptual model from that report.

# 2.1 Geology

Geologic formations observed at the land surface and in the subsurface beneath the Tule Subbasin can be grouped into five generalized geologic units, described below in order of increasing age:

Unconsolidated Continental Deposits – These sediments consist of alluvial, fluvial (i.e., streambed deposits), flood plain, and lacustrine (i.e., lakebed) deposits (labeled "surficial deposits" on Figure 5). The unconsolidated continental deposits range in thickness from 0 ft at the eastern contact with the Sierra Nevada Mountains to more than 3,000 ft near the margins of Tulare Lake in the western part of the Subbasin (see Figure 5; Lofgren and Klausing, 1969). Subsurface alluvial sediments consist of highly stratified layers of more permeable sand and gravel interbedded with lower permeability silt and clay. Clear correlation of individual sand or clay layers laterally across the Tule Subbasin is difficult due to the interbedded nature of the sediments. However, it is noted that the thickness of clay sediments in the upper 1,000 ft below ground surface (bgs) generally increases in the western portion of the Subbasin in the vicinity of Tulare Lake. The unconsolidated continental deposits form the primary groundwater reservoir in the Tule Subbasin.

The lowermost portion of unconsolidated continental deposits is generally correlated with the Tulare Formation. The Tulare Formation is notable in that it includes the Corcoran Clay, a regionally extensive confining layer that has also been referred to as the "E-Clay" (see Figure 5) (Frink and Kues, 1954). The Corcoran Clay consists of a Pleistocene diatomaceous fine-grained lacustrine deposit (primarily clay; Faunt, 2009). In the Tule Subbasin, the Corcoran Clay is as much as 150 ft thick beneath the Tulare Lake lakebed but becomes progressively thinner to the east, eventually pinching out immediately east of Highway 99 (Lofgren and Klausing, 1969).

**Pliocene Marine Deposits** – These sediments underlie the continental deposits and consist of consolidated to loosely consolidated marine siltstone with minor interbedded sandstone beds. The marine siltstone unit thickens to the west, ranging from approximately 500 ft thick near State Highway 65 to more than 1,600 ft beneath Highway 99 (Lofgren and

Klausing, 1969; see Figures 2-5 and 2-6). The marine siltstone beds dip sharply from the base of the Sierra Nevada Mountains on the east to the central portion of the valley in the west. The Pliocene marine strata have relatively low permeability and do not yield significant water to wells.

Santa Margarita Formation – This formation occurs beneath the Pliocene marine strata and consists of Miocene (approximately 5.3 to 23 million years before present) sand and gravel that is relatively permeable and yields water to wells. The formation is approximately 150 to 520 feet thick and occurs at depths ranging from 1,200 feet near State Highway 65 to greater than 3,000 feet beneath State Highway 99. This formation is a significant source of groundwater to wells in the southeastern portion of the Tule Subbasin near the community of Richgrove (Lofgren and Klausing, 1969).

**Tertiary Sedimentary Deposits** – Beneath the Santa Margarita Formation exists an interbedded assemblage of semi-consolidated to consolidated sandstone, siltstone and claystone of Tertiary age (approximately 2.6 to 66 million years before present). Some irrigation wells in the southeastern part of the Tule Subbasin are known to produce fresh water from the Olcese Sand Formation, which is in the uppermost portion of the unit (Ken Schmidt, 2019. Personal Communication). The water quality of the groundwater in the Tertiary sedimentary deposits becomes increasingly saline to the southwest and most of the groundwater in the unit is not useable for crop irrigation or municipal supply except near Highway 65 (Lofgren and Klausing, 1969).

**Granitic Crystalline Basement** – Sedimentary deposits beneath the Tule Subbasin are underlain by a basement consisting of Mesozoic granitic rocks that compose the Sierra Nevada batholith (Faunt, 2009). At depth, the basement rocks are assumed to be relatively impermeable.

There are no significant faults mapped in the Tule Subbasin that would form a groundwater flow barrier or affect groundwater flow.

# 2.2 Hydrology

The hydrology of the model domain includes five significant surface water features (see Figure 6):

#### **Tule River and Lake Success**

The Tule River is the largest natural drainage feature in the Tule Subbasin. From its headwaters in the Sierra Nevada Mountains, the Tule River flows first into Lake Success. Lake Success is a manmade reservoir created by the construction of Success Dam (see Figure 6). Success Dam controls and measures releases of the Tule River. Lake Success is not explicitly included in the

model although releases from the reservoir to the Tule River and Pioneer Canal, as recorded in TRA reports, are the basis for inflows to these surface water features.

Downstream of Lake Success, the Tule River flows through the City of Porterville where it is diverted at various points before flowing into the LTRID. A significant diversion point is the Porter Slough, which flows to the north and semi-parallel to the main river channel and is used to convey surface water to various recharge facilities and canals. Downstream of Porterville, the Tule River ultimately discharges onto the Tulare Lakebed during periods of above-normal precipitation. Stream flow is measured via gages located below Success Dam, at Rockford Station downstream of Porterville, and at Turnbull Weir (see Figure 6).

Releases of water below Lake Success dam are diverted from the Tule River channel at various locations. Diversion points along the river are located at the Porter Slough headgate, Campbell and Moreland Ditch Company, Vandalia Water District, Poplar Irrigation Company, Hubbs and Miner Ditch Company, and Woods-Central Ditch Company. In the water budget, infiltration that occurs in the Porter Slough is included as infiltration from the Tule River. Downstream of the Friant-Kern Canal the Tule River channel is also used as a conveyance mechanism to convey imported water to the Porterville Irrigation District (Porterville ID), LTRID and AWD. Within the Porterville ID and LTRID, a combination of natural stream flow and imported water are further diverted into unlined canals for distribution to artificial recharge basins and farms. Any residual stream flow left in the Tule River after diversions is measured at the Turnbull Weir, located at the west end of the LTRID (see Figure 6).

As streambed infiltration in the Tule River is measured between the various stream gages by the TRA, the Tule River is incorporated into the GFM as part of the recharge package with separate zones delineated between the stream gages where streambed infiltration has been measured.

#### **Deer Creek**

Deer Creek is a natural drainage that originates in the Sierra Nevada Mountains, flowing in a westerly direction north of Terra Bella and into Pixley (see Figure 6). Although the Deer Creek channel extends past Pixley, discharges rarely reach the Tulare Lake lakebed. Stream flow in Deer Creek has been measured at the USGS gaging station at Fountain Springs from 1968 to present time. Friant-Kern Canal water is also diverted into the Deer Creek channel and again measured at Trenton Weir before being delivered to riparian lands via unlined canals (see Figure 6). During wet years, water that reaches the terminus of Deer Creek is discharged into the Homeland Canal.

Deer Creek is included in the GFM as part of the recharge package, with separate zones delineated between stream gages where streambed infiltration has been estimated.

#### White River

The White River drains out of the Sierra Nevada Mountains east of the community of Richgrove in the southern portion of the Tule Subbasin (see Figure 6). Stream flow in the White River has been measured at the USGS gaging station near Ducor from 1972 to 2005. Data after 2005 has been extrapolated. The White River channel extends as far as State Highway 99 but does not reach the Tulare Lake lakebed. All streamflow in the White River that is not lost to evaporation is assumed to become groundwater recharge.

The White River is included in the Tule Subbasin model as part of the recharge package.

#### **Tulare Lake**

During the calibration period (1986 through 2017), Tulare Lake has been a dry lakebed except for localized residual marshes and wetlands and occasional flooding. This surface water feature is not explicitly included in the model.

# 2.3 Hydrogeology

In general, five aquifer/aquitard units comprise the Tule Subbasin:

- 1. Upper Aquifer (Model Layer 1)
- 2. The Corcoran Clay Confining Unit and Other Confining Units (Model Layer 2)
- 3. Lower Aquifer (Model Layer 3)
- 4. Pliocene Marine Deposits (generally considered an aquitard) (Model Layer 4)
- 5. Santa Margarita and Olcese Formations of the Southeastern Subbasin (Model Layer 5)

Detailed descriptions of these aquifers/aquitards are provided in TH&Co (2017b) and TH&Co (2020).

In general, groundwater in the Tule Subbasin flows from areas of natural recharge along major streams at the base of the Sierra Nevada Mountains on the eastern boundary towards a groundwater pumping depression in the west-central portion of the Subbasin (see Figures 7, 8 and 9). The pumping depression has reversed the natural groundwater flow direction in the western portion of the Subbasin, inducing subsurface inflow across the southern and western boundaries. Recharge from the Tule River results in a groundwater flow divide in the upper aquifer along the northern boundary of the Tule Subbasin. As such, upper aquifer groundwater on the north side of the river flows to the north and out of the Subbasin. Groundwater flow patterns in the upper aquifer have generally not changed significantly since the late 1980s (see Figures 7 and 8).

In the lower aquifer, groundwater flows to the southwest toward a pumping depression in the western portion of the Subbasin (see Figure 9). This pumping depression extends from west of Corcoran in the northwest to the Alpaugh area in the southwestern Tule Subbasin west of Highway 43.

Groundwater level changes over time can be observed from hydrographs for wells monitored in the Tule Subbasin. Despite a relatively wet hydrologic period between 1995 and 1999 and periodic wet years (2005 and 2011), groundwater levels in upper aquifer wells show a persistent downward trend between approximately 1987 and 2017 (see Figure 10). Groundwater level trends in wells perforated exclusively in the lower aquifer vary depending on location in the Subbasin (see Figure 11). In the northwestern part of the Subbasin, lower aquifer groundwater levels have shown a persistent downward trend from 1987 to 2017. In the southern part of the Subbasin, groundwater levels were relatively stable between 1987 and 2007 but began declining after 2007.

Comparisons of hydrographs for wells perforated in the upper aquifer with nearby wells perforated predominantly in the lower aquifer show that groundwater levels in the upper aquifer are higher than groundwater levels in the lower aquifer (see Figure 12). This indicates a downward hydraulic gradient and indicates that the upper aquifer is recharging the lower aquifer of the Tule Subbasin. Faunt (2009) has suggested that the recharge of the lower aquifer via wells that are perforated across both aquifers has increased with the number of deep wells constructed in the San Joaquin Valley.

#### 2.4 Land Subsidence

Land subsidence in the Tule Subbasin as a result of lowering the groundwater level due to groundwater production has been well documented (Ireland et al., 1984; Faunt, 2009; Luhdorff and Scalmanini, 2014). Prior to 1970, as much as 12 ft of land surface subsidence was documented for the area immediately south of Pixley (Ireland et al., 1984). As groundwater levels stabilized in the area throughout the 1970s and early 1980s, land subsidence was largely arrested. During this time, monitoring for land subsidence that had previously been conducted along the portion of the Friant-Kern Canal that is within the Tule Subbasin was discontinued.

From the late 1980s into the 2000s, it is suspected that land subsidence in the Tule Subbasin was reactivated as groundwater levels declined. Groundwater flow model simulations of land subsidence in the Central Valley by Faunt et al. (2009), which were calibrated to historical land subsidence that occurred in the 1960s, simulated an additional two to four feet of land subsidence between 1986 and 2003.

The reactivation of land subsidence in the Subbasin was confirmed in the late 2000s based on data from InSAR satellites and one GPS station located in Porterville, California. InSAR data showed

as much as four feet of additional land subsidence occurring in the northwestern portion of the Tule Subbasin between 2007 and 2011 (see Figure 13) (Luhdorff and Scalmanini, 2014). The GPS data showed that approximately 0.4 ft of land subsidence occurred in the Porterville area between 2007 and 2011. From 2015 through 2018, land subsidence in the Tule Subbasin, as observed from InSAR data, continued with as much as 2.75 ft of additional land subsidence in the northwest portion of the Subbasin and as much as 0.75 ft of additional land subsidence at the Porterville GPS station (see Figure 14). GPS data from the Delano, California station, located outside the Subbasin, showed approximately 1 ft of subsidence between 2012 and 2016. Based on benchmarks located along the Friant-Kern Canal and monitored by the Friant Water Authority (FWA), cumulative land subsidence along the canal between 1959 and 2017 has ranged from approximately 1.7 ft in the Porterville area to 9 feet in the vicinity of Deer Creek (see Figure 13).

The rate of land subsidence in the Tule Subbasin varies both spatially, according to the geology of the subsurface sediments and scale of groundwater level declines, and temporally with changes in groundwater levels associated with wet and dry periods. The average rate of change in land surface elevation between 1987 and 2018 for the area of maximum subsidence was estimated to be approximately 12 feet over the 32-year period for a rate of 0.4 ft/yr. At the Porterville GPS station, the annual rate of subsidence between 2006 and 2013 was approximately 0.1 ft/yr but increased to approximately 0.3 ft/yr between 2013 and 2019 (see Figure 14).

#### 3.0 Groundwater Flow Model

## 3.1 Description of Model Codes

The Tule Subbasin groundwater flow model was developed using the numerical groundwater flow model code MODFLOW. MODFLOW is a block centered, finite difference groundwater flow modeling code developed by the USGS for simulating groundwater flow (McDonald and Harbaugh, 1988). MODFLOW is one of the most widely used and critically accepted model codes available (Anderson and Woessner, 1992).

In order to simulate surface water and groundwater interaction, land surface subsidence, and agricultural water budget components in the Tule Subbasin, TH&Co utilized the MODFLOW variant One-Water Hydrologic-Flow Model or MODFLOW-OWHM (Hanson et al.,2014, Boyce et al., 2018, and Boyce et al., in review). Specifically listed in CDWR (2016), this model code is designed to simulate the use and movement of water in irrigated agricultural areas with unmetered pumping and is particularly applicable to the Tule Subbasin where the majority of surface water and groundwater use is for agricultural irrigation.

# 3.2 Model Size and Grid Geometry

The GFM domain is approximately 41 miles in the east-west direction and 36 miles in the north-south direction and encompasses approximately 1,472 square miles at the western base of the Sierra Nevada Mountains in the south-central portion of the San Joaquin Valley Groundwater Basin (see Figures 1 and 2).

The model domain is discretized into 216 columns and 190 rows with 1,000 ft by 1,000 ft cells (see Figure 15). Each model layer is divided into 41,040 cells with a total of 205,200 cells in the entire five-layer model. The site coordinate system for the model was established in NAD 83 State Plane CA Zone 4.

# 3.3 Temporal Discretization

Both recharge and discharge were applied to the GFM in monthly stress periods for the calibration period (October 1986 through September 2017). October 1986 was selected as the starting time to include multiple dry and wet hydrologic periods and to avail the analysis of a previous water budget conducted by TH&Co (2015) that accounts back to 1986. The model period ended in September 2017 which corresponds to the end of the 2016/17 water year because that was the last month of complete surface water data.

## 3.4 Water Budget Areas

The Farm Process Package of MODFLOW accounts for the application, consumption and movement of water at the land surface in irrigated agricultural areas. The surface water budget is coupled with the groundwater flow system in the sense that the applied water demand of any given agricultural area that is not met by surface water supplies (i.e., imported water, diverted streamflow, or precipitation) is assumed to be supplied by pumped groundwater. In the Farm Process Package, agricultural areas can be subdivided to account for differences in crop type, e.g., irrigation efficiency, and available surface water supply, among others. To account for these unique water budget areas, the Farm Process Package (FMP) for the Tule Subbasin model was divided into agricultural water budget areas (referred to as "Farms" in Schmid and Hanson, 2009 and "water budget areas" (WBAs) in subsequent publications [Boyce et al., in review]).

The water budget areas assigned to the GFM are shown on Figure 16. Some of the water budget areas in the Tule Subbasin were delineated to match, or at least resemble, established irrigation districts or GSA political boundaries (e.g., WBAs 9, 11 and 12, which represent LTRID, Pixley Irrigation District and DEID, respectively). Other WBAs were identified for areas of similar crop types or areas not specifically identified with an agency. Agricultural water budgets were developed for each WBA in accordance with the land use and surface water supply data available for those areas.

# 3.5 Agricultural Water Use

Agricultural water use is simulated in the GFM using the FMP. Agricultural water use is a function of the total water demand of any given water budget zone, which is supplied through a combination of precipitation, surface water supplies, and groundwater pumping.

# 3.5.1 Estimates of Total Agricultural Irrigation Demand

Total agricultural irrigation demand is the total water demand necessary to sustain a crop in any given area. It is estimated based on land use data showing the types and areas of crops grown, evapotranspiration estimates for the individual crop types, and assumptions for irrigation efficiency based on the types of irrigation used to supply water to the crops (e.g., spray, drip, row and furrow, etc.).

Information on the types and areas of crops for the LTRID, Pixley Irrigation District, Porterville Irrigation District, and Saucelito Irrigation District were obtained from annual crop surveys from each respective district. The types and areas of crops in other parts of the Tule Subbasin were estimated from land use maps and associated data published by the CDWR for 1993, 1999, 2007 and 2014 (see Figure 17). For the portion of the model in Kern County, land use maps were obtained from CDWR (1990 and 2014) and Kern County Department of Agriculture and

Measurement Standards (1999 and 2007). For the portion of the model in Kings County, land use maps were obtained from CDWR for 1991, 1996, 2003, and 2014.

Consumptive use estimates for the various crop types were based on demands specific to the crops in the Tule Subbasin area, as published in ITRC (2003). The crop consumptive use estimates took into account effective precipitation (i.e. consumptive use associated with precipitation was removed from the total demand resulting in consumptive use associated with irrigation only). Crop types were grouped into the following categories (see Table 1):

- Grain and Grain Hay
- Truck
- Corn and Silage
- Miscellaneous Field Crops
- Grapes
- Cotton
- Deciduous and Fruit Trees
- Alfalfa and Pasture
- Nuts

Where appropriate, crop consumptive use estimates for any given area accounted for double cropping.

Deep percolation of applied irrigation water (i.e., return flow) was estimated based on the irrigation method for each land use type reported in CDWR land use maps. Irrigation efficiencies were applied to the different irrigation methods based on tables reported in California Energy Commission (2006). The irrigation types and their respective efficiencies are as follows:

- Border Strip Irrigation 77.5 percent
- Micro Sprinkler 87.5 percent
- Surface Drip Irrigation 87.5 percent
- Furrow Irrigation 67.5 percent

TH&Co assigned a single crop consumptive use and irrigation efficiency estimate to each water budget zone for any given time period. Each was area-weighted according to the land use in that zone (see Table 2). In order to simulate changes in cropping patterns over time, TH&Co relied on CDWR land use maps for 1993, 1999, 2007, and 2014. TH&Co estimated area-weighted irrigation efficiencies for two time periods: 1986 to 2002 and 2003 to 2017.

Total estimated agricultural irrigation demand for any given time period was based on the areaweighted consumptive use estimate multiplied by the area of the water budget zone divided by the irrigation efficiency.

### 3.5.2 Estimates of Individual Water Supplies to Meet Irrigation Demand

Agricultural irrigation demand is met from three sources: precipitation, surface water deliveries, and groundwater pumping. Consumptive use estimates from ITRC accounted for effective precipitation (see Section 3.5.1). Thus, irrigation demand in the WBAs of the model was met from surface water supplies and groundwater pumping.

Surface water deliveries to crops occur via imported water from the Friant-Kern Canal and other canals in the Subbasin as well as diverted streamflow from the Tule River and Deer Creek. Monthly imported surface water deliveries for WBAs covering Porterville ID, Saucelito Irrigation District, Tea Pot Dome Water District, Alpaugh Irrigation District, Atwell Island Irrigation District, and Terra Bella Irrigation District were obtained from United States Bureau of Reclamation (USBR) Central Valley Operation Annual Reports. Monthly imported water data for LTRID and other agencies was provided by the respective agencies. Monthly surface water deliveries of diverted streamflow from the Tule River are based on TRA annual reports. Monthly surface water deliveries of diverted streamflow from Deer Creek were provided by agencies that divert the water.

Groundwater pumping is estimated in each water budget zone as the balance of the total water demand not met from precipitation and surface water supplies.

Historical agricultural water demand by source is summarized in Appendix A.

# 3.6 Boundary Conditions

Boundary conditions specify groundwater elevations (head boundaries) or flows (flux boundaries, for example pumping wells) near the perimeter and/or within the model domain. Functionally speaking, boundary conditions add or remove water from the groundwater system and can be specified anywhere in the model.

#### 3.6.1 Lateral Model Boundaries

Boundary conditions applied near the perimeter of the model domain include no-flow cells (inactive), recharge points along the base of the Sierra Nevada Mountains, and time-varying specified head cells (see Figure 15). Due to the uncertainty of groundwater flow in the fractured bedrock of the Sierra Nevada Mountains, the portion of the model domain overlying the surface expression of the bedrock in this area was designated as "inactive" and assigned with "no-flow"

cells. Groundwater recharge attributed to subsurface inflow from the mountain-block to the alluvial aquifer system was addressed using recharge points (i.e. injection wells) placed at the base of the mountains within the active model area. Groundwater levels at the north, west and southern Subbasin boundaries are constrained to measured groundwater levels in 29 wells located near the model boundary; 15 wells perforated in the upper aquifer and 14 wells perforated in the lower aquifer (see Figure 15). Groundwater levels in between the control wells were spatially and temporally interpolated for any given monthly stress period. Hydrographs for boundary control wells are provided in Appendix B.

#### 3.6.2 Layer Elevations

Model layers were developed based on analysis of five hydrogeologic cross sections extended through the model domain (see Figures 5, 18, and 19; Plates 1 through 5). The cross sections were developed based on driller's logs, geophysical logs, and well construction information. The top of Layer 1 is the ground surface as imported from USGS DEMs with a horizontal 1 arc-second (approximately 10-meter) resolution and vertical accuracy of approximately 3 meters; these values were averaged for each 1,000 ft x 1,000 ft cell. The boundaries between each model layer were contoured using ESRI ArcMap v. 10.6.1 based on the layer top and bottom elevations from the cross sections and other control points from well logs and geophysical logs.

Model Layer 1 corresponds to the Upper Aquifer. The bottom of Layer 1 was selected to correlate with the top of the Corcoran Clay, where it exists, and is generally shallower than the top of perforations for most wells in the eastern part of the Tule Subbasin. The thickness of Layer 1 ranges from less than 50 feet in an area north of Porterville to approximately 450 feet near Corcoran (see Figure 20). This layer was designated as convertible (i.e., variably unconfined/confined) although given that groundwater levels are always below the land surface, this layer is always unconfined.

Layer 2 corresponds to the Corcoran Clay, where it exists, primarily west of Highway 99 (see Figure 18). The thickness of Layer 2 ranges from approximately 50 feet at the base of the Sierra Nevada Mountains in the eastern model domain to approximately 500 feet in the western part of the model domain (see Figure 21). This layer was designated as convertible such that when groundwater levels are above the top of the model layer, storage properties associated with confined conditions were applied and when groundwater levels are below the top of the model layer, storage properties associated with unconfined conditions were applied.

Layer 3 generally corresponds to the Lower Aquifer. This aquifer ranges in thickness from less than 250 feet at the base of the Sierra Nevada Mountains to approximately 2,000 feet in the northwest model domain (see Figure 22). Like the overlying layers, Layer 3 was designated as convertible.

Layer 4 generally correlates to Pliocene marine sedimentary deposits in the eastern portion of the Tule Subbasin. This layer is generally considered an aquitard separating the overlying Lower Aquifer (Layer 3) from the underlying Santa Margarita Formation aquifer (Layer 5). The thickness of Layer 4 ranges from less than 250 feet along the model edges to greater than 1,700 feet in the south-central model area (see Figure 23). This layer is modeled as confined.

Layer 5 represents the Santa Margarita Formation and upper portion of the Olcese Formation in the eastern part of the Tule Subbasin. The thickness of this layer ranges from 0 to 1,000 feet thick (see Figure 24). The bottom of Layer 5 is a no flow boundary. This layer is modeled as confined.

#### 3.6.3 Groundwater Level Initial Conditions

The initial groundwater level conditions for the start of the model transient period was based on a groundwater contour map of the model domain generated from groundwater levels measured in from October 1986 to March 1990 (see Figure 7).

#### 3.6.4 Groundwater Recharge

#### 3.6.4.1 Agricultural Return Flow - Farm Process Package

Deep percolation and groundwater recharge of applied water from agricultural irrigation (i.e., return flow) was addressed using the FMP. Return flow was simulated using FMP based on the average consumptive use and irrigation efficiency assigned to each water budget zone.

#### 3.6.4.2 Mountain-Block Recharge - Well Package

Subsurface inflow to the alluvial aquifer system from the fractured bedrock along the base of the Sierra Nevada Mountains was simulated using the Well Package (WEL). Thirty-seven injection wells were placed at the base of the Sierra Nevada Mountains along the bedrock alluvial interface to simulate the recharge (see Figure 15). Recharge was directed into Layer 3 of the model. As the contribution of recharge to the alluvial aquifer system from the mountain block is one of the least known aspects of the water budget, recharge rates in the injection wells were varied across a wide range during the calibration process in order to find the optimum recharge rate to achieve model calibration.

## 3.6.4.3 Subsurface Inflow in the Alluvial Channel of the Tule River

Some subsurface inflow of groundwater is expected in the Tule River channel at the eastern boundary of the active model area. This inflow was simulated with a time-varying specified head cell placed at the location of Well 22S/28E-03H01. The specified heads were fixed at the groundwater levels measured in this well for its period of record from October 1986 to February

2008 (see Appendix B). The flows from this boundary condition are represented as the Mountain Block Recharge in the water budget.

## 3.6.4.4 Other Recharge

For all other recharge in the Tule Subbasin Model, recharge was applied to the uppermost active model layer within 71 individual recharge zones using the MODFLOW Recharge Package (RCH). The following sources of groundwater recharge were simulated in the model using the Recharge Package:

- Deep percolation of precipitation
- Streambed infiltration and recharge in the Tule River (including Porter Slough), Deer Creek, and White River channels
- Artificial recharge in basins
- Infiltration in unlined canals
- Areas of septic return flow and urban landscape return flow

## 3.6.5 Groundwater Pumping

Groundwater pumping was simulated using the MODFLOW Multi-Node Well Package (MNW2). For agricultural groundwater production, pumping was assigned to individual wells based on the required pumping demand estimated from the FMP. For most areas of the model, representative wells were placed at mile-square centers and perforated in accordance with the average perforation interval of wells in their respective water budget zone from driller's logs in the CDWR driller's log database (see Figure 25). In the 10-mile corridor centered on the Friant-Kern Canal, a more detailed accounting of actual pumping wells was input with reported perforation intervals in order to provide for a more detailed analysis of land subsidence along the canal. A total of 1406 agricultural wells were included in the model.

For municipal pumping (e.g., City of Porterville) and agency pumping (e.g., Angiola Water District) where the locations and depth intervals of the wells were known or inferred, the wells were included in the model explicitly. A total of 273 municipal or irrigation district wells were included in the model (see Figure 25)

Groundwater production was assigned to each well in the model in monthly stress periods. Agricultural pumping was assigned to individual wells based on the required pumping demand estimated from the FMP. Annual agricultural and municipal groundwater pumping for the period of the model is shown in Figure 26.

## 3.7 Aquifer Characteristics

The propensity of aquifer sediments to transmit and store water is described in terms of transmissivity, hydraulic conductivity, and storativity. The aquifer system of the Tule Subbasin is highly heterogeneous and aquifer permeability and storage characteristics vary greatly both laterally and vertically. Where possible, TH&Co relied on long-term pumping test data to develop initial ranges of aquifer parameter estimates for input to the model (see Table 3). In the absence of this type of test, aquifer parameter estimates were also obtained from analysis of short-term pumping tests, textural analysis obtained from Faunt et al. (2009), and/or assignment of literature values based on the soil types observed in driller's logs. This section describes the aquifer parameters used in the GFM.

### 3.7.1 Transmissivity and Hydraulic Conductivity

Transmissivity is a measure of the propensity for groundwater to flow within an aquifer and was primarily developed for analysis of well hydraulics in confined aquifers (Freeze and Cherry, 1979). Multiple sources of data for estimating transmissivity were obtained, reviewed, and analyzed, including previous modeling efforts (Faunt et al., 2009), other technical reports, and pumping test data from local agencies (Schmidt, 2018). Transmissivity estimates were obtained from pumping test data for 225 wells, 29 of which were perforated only within the Upper Aquifer, 70 of which were perforated only within the Lower Aquifer, and 126 of which were perforated across multiple aquifers. Of the available pumping test data, 43 tests were known to be long-term tests (i.e., 24 hours or greater) and 55 tests were known to be short-term specific capacity tests (see Table 3). Details on the test duration for the remaining 125 wells was unknown.

The permeability of the sediments with respect to a given fluid (in this case, groundwater) in each layer of the model is expressed as hydraulic conductivity. Horizontal hydraulic conductivity is related to transmissivity through the following relationship:

$$K = \frac{T}{b}$$

Where:

K = Horizontal hydraulic conductivity (ft/day);

T = Transmissivity (ft/day); and

b = Aquifer thickness (ft)

Given our configuration of MODFLOW-OWHM, hydraulic conductivity was an input to the GFM whereas transmissivity was not. The distribution of horizontal hydraulic conductivity in each layer

of the model was initially developed based on pumping test data and associated transmissivity estimates, supplemented with interpretation of soil properties through texture analysis, and finalized through the calibration process described in Section 3.8. The initial horizontal hydraulic conductivity distribution of each model layer was developed as a map that included pumping test-derived values overlaid on a visualization of percent coarse sediment by layer from soil textural analysis obtained from Faunt et al. (2009). Higher percentages of coarse-grained sediment were correlated with higher hydraulic conductivity values.

Hydraulic communication between adjacent model layers was addressed through vertical hydraulic conductivity. Because sediments are generally deposited in layers in alluvial/fluvial environments, horizontal hydraulic conductivity is often significantly greater than vertical hydraulic conductivity. Such sediments are said to be vertically anisotropic. Quantification of vertical hydraulic conductivity was accomplished via model calibration as described in Section 3.8. Similarly, the sediments may also be horizontally anisotropic as noted in Neuman et al. (1984) and more recently in Gianni et al. (2019). Like the vertical hydraulic conductivity, horizontal anisotropy was also quantified through model calibration.

## 3.7.2 Storage Properties

The release and uptake of water to and from storage was simulated using specific yield, specific storage, the elastic storage coefficient, and the inelastic storage coefficient. Specific yield and the elastic storage coefficient govern the reversible release and uptake of water whereas the inelastic storage coefficient governs the irreversible release of water due to compaction of porous media.

- Specific yield represents unconfined storage associated with draining or filling of porous media due to changes in the water table. It is defined as the difference between porosity and specific retention, where porosity is associated with the pore space volume and specific retention is associated with that portion of the pore space volume that does not drain.
- Specific storage represents confined storage associated with expansion or compression of both water and soil 'skeleton'. These processes are simulated within MODFLOW-OWHM by considering both elastic (reversible) compression and expansion of the soil skeleton and inelastic (irreversible) compression of the soil skeleton. As the term is used here, inelastic compression is the irreversible reduction in pore space that results in land subsidence.

The values of these storage properties were quantified through model calibration as described in Section 3.8.

## 3.7.2.1 Specific Yield

Layers 1, 2, and 3 of the GFM may be unconfined or confined (i.e., they are specified to be 'convertible' as noted above) depending on groundwater level conditions, which vary transiently throughout the model simulation. The specific yield values for these three uppermost model layers are specified exclusively in the LPF package. Conversely, being specified as confined layers, values of specific yield are not assigned to Layers 4 and 5.

Although previous model studies of the Tule Subbasin provided estimates of specific yield (Ruud et el, 2003; Faunt et al., 2009), to date, there are no measured data with which to estimate specific yield.

## 3.7.2.2 Specific, Elastic, and Inelastic Storage

In MODFLOW, the layer property flow package (LPF) is linked to the subsidence package (SUB) displacements through changes in the elevations of cell-by-cell layer boundaries. Given this linkage, parameters associated with the elastic and inelastic storage are specified in both packages. Specifically, subsidence is computed using the values for specific storage in the LPF package (which have dimensions of 1/ft) and the dimensionless elastic and inelastic storage coefficients in the SUB package. The portion of elastic and inelastic storage associated with the compressibility of water is specified in the LPF package as the 'specific storage' whereas the portion associated with compressibility of the soil skeleton were assigned in the MODFLOW subsidence package. Elastic storage is associated with the reversible compressibility of the soil skeleton whereas inelastic storage is associated with the irreversible compressibility of the soil skeleton.

## 3.7.3 Critical Hydraulic Head

Land subsidence in the SUB package of the model is a function of the effective stress of the aquifer system and changes in hydraulic head.

Non-recoverable (i.e., irreversible or inelastic) land subsidence occurs in the SUB package when the change in effective stress under a given hydraulic head condition exceeds the previous maximum effective stress (or pre-consolidation stress) of the aquifer system. This maximum effective stress can generally be defined by the previous lowest groundwater level (Sneed, 2001), herein referred to as the "critical head."

In order to define the critical head in the Tule Subbasin groundwater model, TH&Co analyzed the previous lowest groundwater level in the Tule Subbasin prior to the start of the model transient period in 1986. In general, this groundwater level condition is indicative of the early to mid-1960s, as documented in Ireland et al., 1984. The historical low groundwater level prior to 1986 in each

calibration target well was used to provide an initial estimate of critical head, which was refined through model calibration.

## 3.8 Model Calibration

As noted in CDWR (2016), model calibration is required by the GSP Regulations (§352.4(f)(2)). Calibration is performed to demonstrate that the model can reasonably reproduce (simulate) historical measurements (e.g., groundwater elevations and land subsidence measurements). Calibration generally involves iterative adjustments of various model parameters until the simulated results reasonably match historical measurements. As their precise values are unknown, aquifer characteristics such as those described in the previous subsection are commonly modified during model calibration. Adjustment of parameter values is constrained within a range of reasonable values through review of aquifer test data, borehole data, hydrographs, and literature data.

The precise values of the numerous aquifer characteristics described in the previous subsection (i.e., horizontal hydraulic conductivity, vertical hydraulic conductivity, horizontal anisotropy, specific yield, specific storage, elastic storage, inelastic storage, and critical head) vary laterally and vertically throughout the Subbasin and are unknown. Therefore, these characteristics were quantified through calibration. Given the functionality provided by MODFLOW-OWHM, consumptive use and mountain block recharge were refined from initial values through calibration.

Given the large number of these 'calibration parameters', their spatial variability within and across model layers, the interconnection between water levels and land subsidence, and the goal of conducting a predictive uncertainty analysis as described in CDWR (2016), 'trial-and-error' calibration (as described in Anderson and Woessner, 1992) was largely abandoned in favor of automated calibration using PEST (Doherty, 2003 and 2015). The GFM was calibrated to both measured groundwater levels and measured changes in land surface elevation.

## 3.8.1 Calibration Targets for Groundwater Levels

Simulated groundwater levels were calibrated to measured data collected between October 1986 and September 2017 in selected monitoring wells throughout the Tule Subbasin. The 32 target wells for the model calibration are shown on Figure 27. The model was specifically calibrated to groundwater level observations from wells perforated exclusively in either model Layers 1, 3, or 4. Calibration to observed groundwater levels in Layer 2 was not conducted due to a lack of observation wells perforated in this layer. Groundwater level data specific to Layer 5 is not available. Other criteria for selection of calibration target wells included:

1. Adequate historical groundwater level record.

2. Relative assurance that the measured data were indicative of static groundwater level conditions.

## 3.8.2 Calibration Targets for Land Subsidence

Land subsidence was calibrated at 45 target locations to Interferometric Synthetic Aperture Radar (InSAR) satellite data (see Figure 28). InSAR is a technique for measuring changes in land surface elevation using two or more radar images of the earth's surface to determine any change in land surface elevation. TH&Co obtained historical InSAR land subsidence data for the 45 target locations from the Jet Propulsion Laboratory (JPL). The 45 target calibration locations are generally evenly space across the Tule Subbasin area at 3- to 4-mile spacings. Data were available for the following periods of time:

- 2007 2011
- 2014 2015
- 2015 2017

TH&Co was also able to calibrate land subsidence to land surface elevation data from two Global Positioning Stations (GPS) located near the Porterville Airport and the City of Delano. Land surface elevation data was available for both stations for the period from November 2005 to May 2018 (see Figure 14).

Calibration of changes in land surface elevation was conducted based on relative changes in land surface elevation rather than actual elevation. Land surface elevation datum was not available at an accuracy that would provide a meaningful reference for calibrating actual land surface elevation. The top of the model is defined based on the USGS DEM, which has a vertical accuracy of plus/minus 3 meters (see Section 3.6.2). In addition, it is possible that the elevation defined by the DEM, which is based on NAVD 88, changed between the time the reference was defined and 1986 (the start of the transient model period). Given these limitations, TH&Co instead calibrated land subsidence based on relative change in land surface elevation indicated by the InSAR data for the three time periods indicated above and the data from the Porterville and Delano GPS stations.

#### 3.8.3 Calibration Process

The general calibration process for the GFM included the following steps:

1. A plausible range of values for each of the 41 parameters was assigned to each of 109 pilot points evenly spaced within Layers 1 through 4 and 53 pilot points evenly spaced within

Layer 5 (see Figure 27). The magnitude of the range assigned to each parameter at each pilot point varied based on the quality of the data in the vicinity of the pilot point. For example, pilot points near wells with controlled pumping test data were given a smaller range than those in areas with no available pumping test data. The input parameter groupings that were adjusted during the calibration process included:

- Horizontal hydraulic conductivity ('kh');
- Vertical hydraulic conductivity ('kv');
- Horizontal anisotropy ('hani');
- Specific yield ('sy');
- Specific storage('ss');
- Elastic storage ('ske');
- Inelastic storage ('skv');
- Critical head ('ch');
- Mountain block recharge (MBR; 'wm');
- Crop consumptive use ('um'); and
- Well radius ('rad').
- 2. Some parameters are expected to be correlated with horizontal hydraulic conductivity ('kh'). Therefore, they were expressed as functions of 'kh' based on literature values and professional judgment within PEST to maintain a reasonable degree of consistency among such parameters. For example, soils with high 'kh' values generally have high 'sy' values; conversely, soils with high 'kh' values generally have low 'ske' values.
- 3. Given the number of pilot points and associated calibration parameters, several thousand MODFLOW-OWHM runs through PEST and its utility programs were required to calibrate the GFM, complete the sensitivity analysis, and provide the information needed for the predictive uncertainty analysis.
- 4. The calibration parameters most sensitive parameters to model outcome (defined as the change to the objective function) are horizontal hydraulic conductivity of Layers 1 through 4 (kh1 through kh4) and specific yield of Layer 1 (sy1).

## 3.8.4 Calibration Results

Using PEST and its associated utility programs, over 200 calibrated models were generated. That is, owing to the non-uniqueness of the solution to hydrogeologic models in general, over 200 different spatial configurations of the calibration parameters that resulted in a calibrated model were generated. Additional calibrated models could have been generated but given the ultimate objective of quantifying the sustainable yield and its uncertainty, having over 200 calibrated models was deemed sufficient. Plan-view plots showing the spatial distribution of the calibration

parameters for all five model layers for one of these calibrated models are provided in Appendix C. Visual inspection of these plots shows the calibrated values to be reasonable given the available Subbasin-specific and literature data (e.g., the calibrated values of horizontal hydraulic conductivity are in generally good agreement with those obtained from pumping tests as shown on the plan-view plots). The range of values for the most sensitive parameter groups (i.e., hydraulic conductivity and specific yield) are as follows:

	Horizontal Hydraulic Conductivity; kh (ft/day)*			Specific Yield; sy (unitless)		
Model Layer	Minimum	Average	Maximum	Minimum	Average	Maximum
1	2	20	160	0.001	0.09	0.25
2	0.01	9	120	0.007	0.06	0.25
3	1	20	200	0.01	0.1	0.25
4	0.1	2	20	Not applicable for confined layer		
5	3	4	5	Not applicable for confined layer		

<sup>\*</sup> The anisotropy ratio is the ratio of horizontal hydraulic conductivity along model columns to that along model rows. It ranged from 0.3 to 3.0.

The range of values for elastic and inelastic storage are provided in the table below.

	Elastic Storage, $S_e$ (unitless)			Inelastic Storage, $S_i$ (unitless)		
Model Layer	Minimum	Average	Maximum	Minimum	Average	Maximum
1	1.00 x 10 <sup>-5</sup>	4.92 x 10 <sup>-5</sup>	2.68 x 10 <sup>-4</sup>	1.00 x 10 <sup>-3</sup>	4.49 x 10 <sup>-3</sup>	6.77 x 10 <sup>-2</sup>
2	1.00 x 10 <sup>-5</sup>	4.71 x 10 <sup>-4</sup>	1.00 x 10 <sup>-3</sup>	1.00 x 10 <sup>-3</sup>	5.17 x 10 <sup>-2</sup>	1.00 x 10 <sup>-1</sup>
3	1.00 x 10 <sup>-5</sup>	6.82 x 10 <sup>-5</sup>	4.61 x 10 <sup>-4</sup>	1.00 x 10 <sup>-3</sup>	5.33 x 10 <sup>-3</sup>	3.57 x 10 <sup>-2</sup>
4	1.27 x 10 <sup>-5</sup>	1.29 x 10 <sup>-4</sup>	6.62 x 10 <sup>-4</sup>	1.00 x 10 <sup>-3</sup>	2.61 x 10 <sup>-2</sup>	1.00 x 10 <sup>-1</sup>
5	1.20 x 10 <sup>-5</sup>	8.53 x 10 <sup>-5</sup>	3.17 x 10 <sup>-4</sup>	1.14 x 10 <sup>-3</sup>	9.74 x 10 <sup>-3</sup>	4.65 x 10 <sup>-2</sup>

Model calibration is typically judged using qualitative and quantitative methods. At first, a qualitative visual comparison of simulated groundwater elevations and subsidence rates to measured values was performed. Upon achieving visually acceptable results, quantitative methods as presented in the subsections below were applied to further evaluate the quality of the calibration. Finally, from a water accounting perspective, water budget errors are expected to be less than 1 percent (Hill and Tiedeman, 2007; Anderson and Woessner, 1992). The numerical water budget error for the final calibration was 0.1 percent, which is within the limits of acceptable error.

#### 3.8.4.1 Groundwater Elevations

Calibration hydrographs showing both measured and model-generated groundwater elevations are provided in Appendix D. The simulated groundwater elevations reasonably match the measured elevations at most of the target wells in the model. A scatter plot of simulated versus measured groundwater elevations for the 1,371 groundwater level observations in the calibration is shown in Figure 29. The correlation coefficient between the simulated and measured values is 0.95, which is an acceptably large value that exceeds the benchmark value of 0.90 noted in CDWR (2016) and Hill and Tiedemann (2007).

Another common measure of model calibration is the normalized root mean squared error (NRMSE). The 'error' is the difference between the simulated head value and the measured head value. The error is referred to as the 'residual' and the RMSE, which is normalized by the measured range of groundwater elevations in the model ('range').

$$NRMSE = \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}R_{i}^{2}}}{range}$$

Where:

n = Number of observations; and

R = Residual (ft).

The NRMSE is expressed as a percent with results less than 10 percent generally considered to be acceptable. The NRMSE for the GFM with respect to groundwater elevations is at an acceptably low value of 6.6 percent (see Figure 29).

## 3.8.4.2 Land Subsidence

Calibration graphs showing both measured and simulated subsidence are provided in Appendix E. The simulated land subsidence reasonably matches that measured at the Porterville and Delano GPS stations and via satellite at most of the target locations. A scatter plot of simulated versus measured land subsidence for the 2,616 observations in the calibration is shown in Figure 30. The correlation coefficient between the simulated and measured values is at an acceptably large value of 0.94 and the NRMSE for the GFM with respect to land subsidence is at an acceptably low value of 6.5 percent (see Figure 30).

Given the nature of the subsidence data to which the GFM is calibrated, simulated land subsidence by the model is acceptably calibrated to enable projections of relative change in land surface elevation in the future (e.g. 2.1 feet of subsidence). It is not recommended to determine absolute values of projected land surface elevation.

# 3.8.4.3 Calibration Summary

Based on the acceptably low water budget error and NRMSE values along with the acceptably high correlation coefficients, the GFM is acceptable for its intended use to estimate the future water budget, project future groundwater level changes, and estimate relative changes in future land elevation for evaluating projects and managements actions and estimating the Sustainable Yield of the Subbasin.

The resulting surface and groundwater budgets produced by the calibrated model are presented in Tables 4a, 4b, and 5. A detailed description of the individual water budget items can be found in the Tule Subbasin Setting document (TH&Co, 2020).

# 4.0 Future Subbasin Management Scenario for Analysis with the Model

In order to evaluate planned projects and management actions of each of the six GSAs within the Tule Subbasin, refine the sustainable yield and develop a future water budget for inclusion in the Subbasin Setting document of the GSPs, TH&Co analyzed a future subbasin management scenario with the calibrated GFM. The future scenario began in October 2017 (the end of the model calibration period) and extended through September 2070 and utilized yearly (i.e., water year) stress periods. Projects and management actions were incorporated into the GFM starting in 2020. The purpose for analyzing the scenario was to assess the sustainability of the planned actions, assess the interaction of the planned actions on groundwater levels between the GSAs, and estimate the sustainable yield of the Subbasin.

## 4.1 Projects and Management Actions

Projects for incorporation in the future scenario were provided by basin managers from each of the six Tule Subbasin GSAs (see Table 6). Most of the projects involve increases in recycled water recharge, increased basin recharge, changes in water deliveries, capture of flood water, and water banking operations.

Management actions for incorporation into the model were focused on the reduction in crop consumptive use necessary to achieve sustainability (see Table 7). The reduction in crop consumptive use is directly correlated to a reduction in irrigated water demand and groundwater pumping. Each GSA provided a schedule to reduce consumptive use, starting in 2020, in order to achieve sustainable groundwater pumping by 2040. As the availability of surface water supplies from imported water and diverted streamflow is different between the GSAs, each GSA established a different consumptive use reduction, or "transitional pumping," schedule (see Table 7).

# 4.2 Assumptions for Municipal Pumping

Future projections for municipal pumping were applied to the City of Porterville. Other cities and communities (e.g., Tipton, Richgrove, etc.) were assumed to continue 2017 pumping rates into the future.

# 4.3 Assumptions for Hydrology and Surface Water Deliveries on Major Streams

Baseline stream flow hydrology for the Tule River, Deer Creek and White River for the future projection model was based on the 20-yr average of historical stream flows measured or estimated between water years 1990/91 and 2009/10. This base period approximates the 115-year average

surface water flow within the Tule River between 1903/04 and 2016/17 (TRA 2018 Annual Report, Appendix). Baseline surface water deliveries to agencies with diversion rights in the future projection were also based on the 20-yr average of deliveries for the period 1990/91 to 2009/10.

The baseline streamflow on the major streams used in the future projection for the model were adjusted to account for projections of future climate change. Adjustments were applied based on output from the DWR's CalSim-II model, which provided adjusted historical hydrology for major drainages based on scenarios recommended by the California Department of Water Resources Climate Change Technical Advisory Group (2015). Climate change adjustments to hydrology and surface water deliveries were applied over two time periods within the SGMA planning horizon, as defined by California Water Commission (2016):

- 1. A 2030 central tendency time period, which provides near-term projections of potential climate change impacts on hydrology, centered on the year 2030, and
- 2. A 2070 central tendency time period, which provides long-term projections of potential climate change impacts on hydrology, centered on the year 2070.

Change factors for the 2030 and 2070 central tendency time periods are shown for the hydrology associated with the Tule River historical baseline time period of 1990/91 to 2009/10 on Figure 31. Both the annual change factors and weighted average change factors are shown. In the future projection scenario for the model, TH&Co used the average 2030 change factor for each major stream providing water within the model domain (see Figure 32). The climate adjusted hydrology for these major streams after applying the 2030 change factors ranges from 98 percent to 101 percent of the historical baseline average. The climate adjusted hydrology after applying the 2070 change factors ranges from 95 percent to 101 percent of the historical baseline average. The 2030 central tendency change factors were applied to the future projection scenario from 2025 to 2049. The 2070 central tendency change factors were applied to the future projection from 2050 to 2070.

# 4.4 Assumptions for Friant-Kern Canal Deliveries

Projected surface water deliveries from the Friant-Kern Canal were based on climate adjusted historical average deliveries from 1990/91 to 2009/10 provided by the Friant Water Authority (FWA, 2018 and supporting Excel files). It is noted that the climate adjusted historical FWA data extended only to 2002/03. Thus, it was necessary to estimate the climate adjusted deliveries for 2003/04 through 2009/10 based on proxy years according to the following schedule:

- 2003/04 1946/47
- 2004/05 1935/36
- 2005/06 1939/40
- $\bullet$  2006/07 1975/76

- 2007/08 2001/02
- 2008/09 1963/64
- 2009/10 1950/51

The proxy years were selected based on years when the inflow to Success Reservoir was as close as possible.

The climate adjusted deliveries to each agency included Class I, Class II, and 16B deliveries. Climate adjusted deliveries were also adjusted to account for impacts to deliveries as a result of the San Joaquin River Restoration Project (SJRRP) implementation. All climate change and SJRRP adjustments were applied starting in 2025. Deliveries from the Friant-Kern Canal between 2020 and 2025 were based on the 20-year historical baseline based on 1990/91 to 2009/10. Climate change and SJRRP adjustments were phased in between 2025 and 2030 through a linear interpolation between 2025 baseline deliveries and full application of FWA adjusted deliveries in 2030. TH&Co applied the 2070 central tendency time period climate-related adjustments to imported water deliveries in the Tule Subbasin model projection for the period from 2050 to 2070.

Results of the climate adjustments show that future water deliveries are projected to be generally comparable to historical water deliveries for DEID, KTWD, and Tea Pot Dome WD. Future water deliveries for Porterville ID and Terra Bella ID are projected to increase relative to historical deliveries primarily due to a reduction or elimination of sales and/or transfers that historically occurred. Future water deliveries for LTRID are projected to decrease relative to historical deliveries due to the high proportion of Class 2 supplies which are most impacted by the FWA analysis. Finally, future water deliveries for Saucelito ID are projected to decrease relative to historical deliveries due to changes in sales and/or transfers. Results of the analysis are summarized on Figure 33.

## 5.0 Analysis of the Future Subbasin Management Scenario

TH&Co used the calibrated GFM to analyze the consumptive use that can be accommodated in the future, given each GSA's planned projects and management actions, without a long-term, subbasin-wide net negative change in groundwater storage. Consumptive use is linked to groundwater pumping (and, therefore, change in groundwater storage) as described in Section 3.5.

While the projects and management actions developed for the future projection scenario provided a conceptual schedule for reduction in consumptive use, they cannot provide the consumptive use necessary to make the Subbasin sustainable. Through an iterative process, the consumptive use in the future projection of the model was adjusted until there was no net negative change in groundwater storage from 2040 to 2050¹. During this process, neither streamflow diversions nor imported water deliveries were modified from their projected values; the only changes were consumptive use and associated groundwater pumping. In order to maximize the available consumptive use in the Subbasin while avoiding a net negative change in storage, the target consumptive use in all WBAs, and therefore the transitional pumping schedule, was incrementally reduced from an initial condition that resulted in a negative change in storage to one that resulted in no net negative change in storage. The resulting sustainable level of consumptive use was estimated to be approximately 65,000 acre-ft/year. Additional consumptive use can be supported in any given area of the Subbasin by streamflow diversions and imported water supplies, where available.

# 5.1 Projected Groundwater Budget

The projected surface water and groundwater budgets, based on the future basin management scenario and sustainable consumptive use target for the Tule Subbasin, are shown in Tables 8a, 8b, and 9. The tables are based on the 50<sup>th</sup> percentile sustainable yield representation of the calibrated GFM. As shown in Table 9 the average annual projected change in groundwater storage between 2040 and 2050, after full implementation of transitional pumping, is positive 900 acre-ft/yr.

# 5.2 Projected Groundwater Levels

Projected groundwater level trends at calibration target wells within the Tule Subbasin are provided in Appendix F. All projected groundwater levels were generated using the 50<sup>th</sup> percentile sustainable yield representation of the calibrated GFM. As shown, groundwater levels simulated after 2040 level out for most of the upper and lower aquifer wells relative to their historical and transitional pumping downward trends. Exceptions are upper aquifer wells in the western part of

<sup>&</sup>lt;sup>1</sup> Stress periods in the future projection portion of the GFM are based on water years (i.e. October 1 through September 30) and all results are presented as water years (i.e. 2020 is October 1, 2019 through September 30, 2020).

the Subbasin (e.g., Angiola G1 and 32K01) where downward groundwater level trends continue beyond 2040.

## 5.2.1 2020 - 2040 Transitional Pumping Period

Projected changes in groundwater levels in the upper aquifer (Layer 1) for the transitional pumping time period from 2020 to 2040 are shown on Figure 34. As shown, groundwater levels are below the bottom of Layer 1 throughout much of the eastern portion of the Subbasin, except in the Porterville area where groundwater levels are above the bottom of the layer and projected to remain relatively stable during the transitional pumping period. Groundwater levels in this layer are projected to decline another 100 to 120 feet in the central portion of the Subbasin during the transitional pumping period. Layer 1 groundwater levels in the western portion of the Subbasin are projected to decline another 40 to 80 feet during the transitional pumping period.

Projected changes in groundwater levels in the lower aquifer (Layer 3) for the transitional pumping period from 2020 to 2040 are shown on Figure 35. Layer 3 groundwater levels in the eastern and southeastern parts of the Subbasin are projected to rise. Groundwater levels in the central and northwest parts of the Subbasin are projected to decline another 20 to 40 feet in Layer 3.

## 5.2.2 2040 - 2050 Sustainability Period

Projected changes in groundwater levels in the upper aquifer (Layer 1) for the time period from 2040 to 2050 are shown on Figure 36. Groundwater levels in Layer 1 during this time period are relatively stable throughout the Tule Subbasin, with slight groundwater level rise predicted for the Porterville area. In Layer 3 (Figure 37), groundwater levels show increases of 20 to 40 feet in the eastern portion of the Subbasin and stable to slightly decreasing groundwater levels in the western portion of the Subbasin.

## 5.2.3 2050 – 2070 Sustainability Period with Extended Climate Adjustments

Projected changes in groundwater levels in the upper aquifer (Layer 1) for the time period from 2050 to 2070 are shown on Figure 38. Groundwater levels in Layer 1 during this time period trend downward again in the central portion of the Tule Subbasin, with slight groundwater level rise predicted for the Porterville area. In Layer 3 (Figure 39), groundwater levels are predicted to remain stable during this time period with increases of 20 to 40 feet in the eastern portion of the Subbasin. It is noted that the 2070 central tendency climate adjustments were applied during this time period, which reduce the amount of surface water deliveries available to the GSAs and result in downward trends in groundwater levels in Layer 1.

## 5.3 Projected Land Subsidence

Projected groundwater level trends at calibration target wells within the Tule Subbasin are provided in Appendix G. As land subsidence is correlated with groundwater level decline, continued land subsidence is expected during the transitional pumping period from 2020 to 2040 as groundwater levels continue to drop in the central and northwest parts of the Subbasin (see Figure 40). As much as eight feet (average of 0.4 ft/yr) of additional land subsidence is predicted in the northern Tri-County Water Agency GSA, western Pixley Irrigation District GSA, and northern LTRID GSA. Up to four feet (average of 0.2 ft/yr) of land subsidence is also predicted beneath the Friant-Kern Canal between Deer Creek and White River (see Figure 40).

Between 2040 and 2050, the rate of land subsidence decreases as groundwater levels stabilize throughout most of the Subbasin (see Figure 41). Up to three feet (average of 0.3 ft/yr) of land subsidence is still predicted to occur in isolated areas of the northern Tri-County Water Agency GSA, western Pixley Irrigation District GSA, and northern LTRID GSA. Less than 0.5 feet (average of 0.05 ft/yr) of land subsidence is predicted in the vicinity of the Friant-Kern Canal during this time period.

Land subsidence between 2050 and 2070 is predicted to continue in the western part of the Tule Subbasin as a result of declining groundwater levels in Layer 1 in this area (see Figure 42). Up to four feet (average of 0.2 ft/yr) of land subsidence is predicted during this time period for the northern Tri-County Water Agency GSA at the western boundary of the Subbasin. Up to three feet (average of 0.15 ft/yr) of additional land subsidence is predicted for the southern Tri-County Water Agency GSA and Alpaugh Irrigation District GSA areas.

#### 5.4 Sustainable Yield

The sustainable yield of the Tule Subbasin is a function of the overall water balance of the area. Changes in surface water/groundwater inflow to the basin and surface water/groundwater outflow from the basin impact the sustainable yield. As groundwater management and land use changes impact the water balance, they also impact the sustainable yield. A generalized expression of the water balance is as follows:

$$Inflow - Outflow = +/- Change in Storage$$
 (1)

The water balance equation for pre-developed conditions (prior to human occupation) can be further expressed as:

$$(I_{pr} + I_{str} + I_{ss} + I_{mb}) - (O_{ss} + O_{et}) = \Delta S$$
 (2)

#### Where:

I<sub>pr</sub> = Inflow from Areal Recharge of Precipitation

I<sub>str</sub> = Inflow from Infiltration of Runoff in Stream Beds

 $I_{ss}$  = Inflow from Subsurface Underflow

I<sub>mb</sub> = Inflow from Mountain-Block Recharge

 $O_{ss} = Subsurface Outflow$ 

 $O_{et} = Evapotranspiration$ 

 $\Delta S$  = Change in Groundwater Storage

Under pre-developed conditions, the Subbasin would be in a state of equilibrium such that the inflow and outflow would balance and there would be no significant long-term change in storage assuming a static climatic condition. Under this condition, groundwater levels would be relatively stable.

Under developed land use conditions, the water balance changes as groundwater is pumped from the basin for irrigation and municipal supply, diversions of streamflow occur, and imported water is delivered to the Subbasin. Lowering of the groundwater table resulting from pumping reduces the amount of groundwater that would otherwise leave the Subbasin and reduces evapotranspiration losses in areas of shallow groundwater (e.g., Tulare Lake). Some of the pumped groundwater used for irrigation infiltrates past the roots of the plants and returns to the groundwater as return flow. Water imported into the area is applied to crops but some is lost as infiltration in unlined canals and as return flow. Groundwater return flow also occurs as a result of discharges from individual septic systems. Inflow from the compression of aquitards as a result of subsidence also contributes water to the aquifer system. Other sources of recharge to the groundwater under developed land use include wastewater treatment plant discharges and artificial recharge in spreading basins.

The water balance equation for developed land use conditions can be modified as follows (flows in **bold** are not included in the sustainable yield):

$$(I_{pr} + I_{str} + I_{can} + I_{ar} + I_{rfgw} + I_{rfimp} + I_{com} + I_{ss} + I_{mb}) - (O_{ss} + O_{et} + O_p) = \Delta S$$
(3)

Where:

 $I_{can}$  = Inflow from Canal Losses

 $I_{ar}$  = Inflow from Artificial Recharge

I<sub>rfgw</sub> = Inflow from Return Flow of Applied Water from Groundwater Pumping

 $I_{rfimp}$  = Inflow from Return Flow of Applied Water from Imported Water

I<sub>com</sub> = Inflow of Water Released from Compression of Aquitards

O<sub>p</sub> = Outflow from Groundwater Pumping

If the inflow terms exceed the outflow terms, then the groundwater in storage increases (become positive) and groundwater levels rise. If the outflow terms exceed the inflow, then the groundwater in storage decreases (become negative) and groundwater levels drop. It is assumed that the sustainable yield of the Tule Subbasin is the long-term average groundwater pumping rate, under projected land use conditions, that results in no significant long-term net negative change in groundwater storage in the basin. Based on this premise, the water balance equation can be rearranged and simplified to estimate sustainable yield:

Sustainable Yield = 
$$\Delta S + O_p - I_{can} - I_{ar} - I_{rfimp} - I_{com}$$
 (4)

Thus, if the change in groundwater storage over the planning period is zero and there is no imported water or release of water from compression of aquitards, then the sustainable yield is equal to the pumping. This relationship is valid if the following conditions are met:

- 1. The sustainable yield incorporates a hydrology that is representative of a relatively long period of record that includes multiple wet and dry hydrologic cycles.
- 2. The land use conditions are representative of the time period.

The sustainable yield can also be expressed as all of the components of the water balance not explicitly expressed in Equation 4:

Sustainable Yield = 
$$I_{pr} + I_{str} + I_{rfgw} + I_{ss} + I_{mb} - O_{ss}$$
 (5)

It is noted that the Tule Subbasin Technical Advisory Committee has determined that recharge to the Tule Subbasin associated with the delivery of imported water and the diversion of water from the Tule River and Deer Creek associated with Pre-1914 water rights will not be included in the sustainable yield of the Subbasin. This includes canal losses from delivery of imported water and diverted stream flow, deep percolation of applied imported water and diverted stream flow, and managed recharge in basins.

Applying Equations 4 and 5 to the historical water budget of the Tule Subbasin does not result in a representative sustainable yield because the Subbasin was in overdraft during the historical water budget period. Groundwater pumping depressions that have developed in the western portion of

the Subbasin have historically captured groundwater that would have otherwise left the Subbasin. This increase in groundwater inflow and decrease in groundwater outflow resulted in an apparent sustainable yield that was higher than was actually sustainable. Further, some of the return flow associated with historical overdraft contributed to the unrealistically high historical sustainable yield. The apparent sustainable yield based on the water budget from water year 1990/91 to 2009/10 was reported to be approximately 258,000 acre-ft/yr (TH&Co, 2017b). However, since the downward groundwater trends that resulted in this condition are not sustainable, the associated sustainable yield from this water budget is not representative.

The sustainable yield of the Tule Subbasin will change in the future as a result of changes in groundwater levels and flows associated with planned projects and management actions and changes in deep percolation of applied water (i.e., return flow) from reduced groundwater pumping. This necessary action will change the water budget by not only decreasing outflow from groundwater pumping but also reducing deep percolation of applied water (return flow) and changing the dynamics of inflow and outflow at the Subbasin boundaries. This new water budget regime will result in a sustainable yield that is different from what was realized historically. The projected groundwater budget from the analysis of the future basin management scenario using the calibrated groundwater flow model was the basis for the sustainable yield estimate of the Tule Subbasin. This analysis resulted in a sustainable yield of 130,000 acre-ft/yr.

# 5.5 Uncertainty Analysis

To paraphrase from CDWR (2016), gaining a sense of the magnitude of the uncertainty in model predictions allows decision makers to accommodate the reality that model results are imperfect forecasts and actual subbasin responses to management actions will vary from those predicted by modeling. To this end, output from PEST and its associated utility programs were used to address the uncertainty in estimates of sustainable yield for the Subbasin and subsidence along the Friant-Kern Canal. This approach provided 240 calibrated versions ('realizations') of the GFM. Each realization was comprised of different configurations of aquifer parameters, consumptive use, and mountain block recharge.

## 5.5.1 Uncertainty in Sustainable Yield Estimate

The future water budgets from each of the 240 calibrated realizations of the model were processed, based on Equation 5 in Section 5.4, to produce sustainable yield estimates for each year of the 50-yr implementation and planning horizon (2020 to 2070). Of the original 240 model realizations, 175 resulted in a projected average annual change in groundwater storage greater than -5,000 acre-ft/yr. The 50<sup>th</sup> percentile sustainable yield for the time period from 2040 to 2050 was used as the sustainable yield for the 175 model realizations resulting in greater than -5,000 acre-ft/yr of annual storage change. The 175 estimates of sustainable yield are normally

distributed (see Figure 43). The time period from 2040 to 2050 was selected because it occurs after all planned projects and management actions have been implemented but before the time when the less reliable long-term climate change adjustments to hydrology and water deliveries are applied to the projected water budget (2050).

The projected future sustainable yield of the Tule Subbasin, which is the 50<sup>th</sup> percentile of the distribution of estimates derived from the uncertainty analysis, is estimated to be approximately 130,000 acre-ft/yr (see Table 10). The plausible range of sustainable yield was selected as the values between the 20<sup>th</sup> and 80<sup>th</sup> percentile, resulting in a range of approximately 108,000 to 162,000 acre-ft/yr (see Figure 43). The projected sustainable yield does not include:

- Diverted Tule River water canal losses, recharge in basins, and deep percolation of applied water,
- Diverted Deer Creek water canal losses, recharge in basins, and deep percolation of applied water.
- Imported water canal losses, recharge in basins, and deep percolation of applied water, and
- Deep percolation of applied recycled water and recycled water recharge in basins.

As the groundwater model predicts some continued land subsidence in the Tule Subbasin between 2040 and 2050, there is a contribution of approximately 18,000 acre-ft/yr of water to the aquifer from the compression of aquitards during this time period (see Table 9). This contribution is included in the water budget that results in no net negative change in groundwater storage over the time period. The implication for this is that the sustainable yield for the Subbasin is somewhat lower than reported because the contribution of water to the aquifer from compression of aquitards is not sustainable. Nonetheless, given the uncertainty in model results, the current estimate of 130,000 acre-ft/yr is recommended until more data are collected and the model is updated.

## 5.5.2 Uncertainty in Friant-Kern Canal Subsidence

The 240 realizations of the GFM were also used to assess the uncertainty in simulated land subsidence along the Friant-Kern Canal for the future subbasin management scenario. The target period for this assessment is the 2020 to 2040 transitional pumping period. Figure 44 displays the uncertainty in simulated subsidence at various milepost locations along the Canal using 'box-and-whisker' diagrams. These diagrams show various statistics for simulated subsidence. Specifically, the top of the 'box' portion (the brown-shaded, vertically-oriented rectangle) is the 25<sup>th</sup> percentile whereas the bottom is the 75<sup>th</sup> percentile. Within the box is a horizontal line (i.e., the 50<sup>th</sup> percentile or 'median') and an 'X', which identifies the arithmetic average (i.e. 'mean') value. The top and bottom of each whisker represents the 'local minimum' and 'local maximum' values. These 'local' statistics are those associated with the simulated values after outliers are removed. Outliers are

defined as those values less than or greater than 1.5 times the interquartile range (i.e., 1.5 times the difference between the 25<sup>th</sup> and 75<sup>th</sup> percentile values).

Considering the simulated subsidence shown on Figure 44 for the two locations between Milepost 106 and 108, the plot shows the simulated values to range from 1.0 to 5.1 feet and 1.6 to 4.6 feet for the northern and southern locations, respectively.

For comparison, the simulated land subsidence associated with the realization for the 50<sup>th</sup> percentile sustainable yield (shown as the continuous thick black line extending from left to right across the figure) is approximately 3.2 feet at both locations. Considering the southern location (i.e., closer to Milepost 108), this value roughly corresponds to the 75<sup>th</sup> percentile. That is, the simulated subsidence for 25 percent of the 240 realizations (60 realizations) for this location exceed 3.2 feet. The simulated subsidence associated with the realization for the 50<sup>th</sup> percentile sustainable yield exceeds the median subsidence value at those locations with the highest simulated medians (i.e., those located between Milepost 105 and Milepost 108).

# 6.0 Summary of Findings

A calibrated numerical groundwater flow model has been developed for the Tule Subbasin in support of informing GSPs for the six GSAs within the Subbasin. The model has been calibrated to industry standards with respect to both groundwater levels and land subsidence and is sufficient for informing future potential groundwater level and land surface elevation changes associated with planned projects and management actions. The calibrated groundwater flow model was used to assess a future groundwater budget and determine a sustainable yield for the Tule Subbasin based on planned projects and management actions that resulted in no net negative change in groundwater storage for the ten-year period after the 2040 SGMA sustainability deadline.

The following summarizes the findings from the model analysis:

- The sustainable yield of the Tule Subbasin is estimated to be approximately 130,000 acre-ft/yr. The sustainable yield does not include recharge from imported water delivery losses, recharge in basins and return flow; recharge from surface water diversion from the Tule River and Deer Creek associated with delivery losses, recharge in basins and return flow; and recharge of recycled water return flow and recharge in basins.
- Uncertainty analysis indicates that the plausible range of sustainable yield is approximately 108,000 to 162,000 acre-ft/yr.
- The future sustainable yield of the Subbasin is lower than the historical sustainable yield as a result of reduced irrigation return flow, reduced subsurface inflow, and increased subsurface outflow along the subbasin boundaries.
- The amount of crop consumptive use that can be supported by the sustainable yield is estimated to be approximately 65,000 acre-ft/yr with additional consumptive use supported by streamflow diversions and imported water supplies, where available.
- Although the overall water budget for the Tule Subbasin is projected to be in balance between 2040 and 2050, there are areas of the Subbasin where groundwater levels are still projected to decline through the planning horizon. It is anticipated that these localized areas of recharge and discharge imbalance can be addressed through basin management actions in the individual GSAs in which they occur.
- As much as approximately four feet of additional land subsidence is projected to occur beneath the Friant-Kern Canal during the transitional pumping period from 2020 to 2040. The greatest land subsidence is projected to occur in the area of the canal between Deer Creek and White River.
- Land subsidence is projected to be arrested after 2040 throughout most of the Tule Subbasin as a result of projected stabilizing of groundwater levels. Continued land subsidence is projected in the northwestern portion of the Subbasin and in the northern
